Figure 2 represents the opposite condition to that discussed for Figures 1, 4, and 5 in that all of the zero sequence comes from the far end of the line so that the relays are operable from positive and negative sequence currents only. Since the result of this study can be applied in reverse to cover fault location 2 in Figure 4, it is important that all directional elements associated with fault detecting elements (such as overcurrent elements, impedance elements, and so forth) receiving enough current to operate should give a correct indication. The study of Figure 2 does not repeat the consideration of phase-to-phase and 3-phase faults, as in this respect, Figure 2 is a duplicate of Figure 1.

Figure 3 represents a typical condition wherein a delta star connected transformer bank is interposed between the relay location and the fault. Here again, it is important that all directional elements associated with fault detecting elements receiving enough current to operate should give a correct indication inasmuch as the conditions affecting the relays of Figure 3 may be applied in reverse to other relays at bus G protecting source circuits feeding into bus G.

The study of Figure 3 has been based on the connections as shown schematically in that the star side of the bank is connected to the line. Further, the line voltages X, Y, Z, lead the bus voltages A, B, C by 30 degrees in accordance with American Standards Association standard practice based on the line having the higher voltage. Other combinations were

considered, such as star (low-voltage) to delta (high-voltage), and with the non-standard condition of the 30-degree lagging relationship. It was found that the same results were obtained, the only difference being that when the 30 degree lagging connections were used, the formulas became associated with relays for different phases. Hence it follows that what is the best connection for Figure 3 also is the best for the other possible transformer connections.

The Search for Limits

With the formulas derived as shown in Tables I, II, and III it became desirable to analyze these formulas to determine the maximum spread in phase angle between the current and the voltage. The results of this study are shown in Tables V, VI, and VII. Several of the vector diagrams in these tables will now be discussed in order to clarify the method of analysis used as well as the peculiar notation used with the diagrams. Dash lines in the table mean that that particular relay received no current for the fault in question. Blank spaces in the B and C relay columns for the 3-phase fault, ABC, indicate that the consideration given one relay, relay A, is sufficient.

Remembering that Table V is associated with Table I and Figure 1, it is determined that the diagram for relay B, line 1 (90-degree connection, phase-B-to-C fault) comes from the formula

$$Z_D = \sqrt{3}Z_{1S}\angle 270^\circ + 2Z_{1L}\angle 240^\circ \qquad (2)$$

The angle of Z_D is the angle by which the current lags the voltage, so that the current vector will be plotted clockwise from the reference voltage vector by whatever positive angle results from evaluating equation 2. The impedance terms Z_{1S} and Z_{1L} are the positive sequence impedances of the source and the line, respectively. The expressions $\angle 270^\circ$ and $\angle 240^\circ$ are mathematical operators producing a positive angular rotation of the amount indicated. In this particular formula, $-j$ could have been used for $\angle 270^\circ$ and the a^2 operator of symmetrical components could have been used for $\angle 240^\circ$. These two substitutions were not made, however, because so many of the other formulas contain operators in steps of 30 degrees that is was considered preferable to keep all of the operators in this form.

Equation 2 is to be studied for limits. One limit is apparent immediately in that if the fault is close enough, Z_{1L} becomes zero and all that is left is $\sqrt{3}Z_{1S}\angle 270^\circ$.

The source cannot have an angle greater than 90 degrees, so if we take 90 degrees for the angle of the source impedance and rotate it by $\underline{/270°}$, the answer comes out at an angle of 360 or zero degrees. This is the characteristic angle of Z_D and thus means that the current and voltage are in phase. Referring to the vector diagram in Table V, it will be seen that a current vector has been drawn in phase with the voltage vector, and the notation for it is *S*90. This notation means that the source impedance (*S* for source) governs for this limit, and that it has an angle of 90 degrees.

Assume that the source impedance has an angle of 60 degrees. Adding 60 to 270 degrees yields 330 degrees, meaning that the current lags the voltage by 330 degrees (leads by 30 degrees) and such a current vector would fall in the shaded area, not establishing a limit, and hence was not plotted.

For this case, equation 2, the maximum possible angular position was found by assuming that the fault is close in and involves an arc of great length so that the impedance of the line is not only at 0 degrees, but also so large that the impedance of the source becomes negligible. In this case, through neglecting Z_{1S}, the expression for Z_D is evaluated by considering the second term of equation 2, or $2Z_{1L}\underline{/240°}$, and with Z_{1L} having its own angle of zero degrees, it follows that the current leads the voltage by 120 degrees.

Another current vector is shown accordingly in the vector diagram, and wherein the notation *LO* signifies that the line impedance governs and that it has an angle of zero degrees. It was felt that it was a bit pessimistic to lean too heavily on the limit thus established because this calls for the arcing fault to absorb the entire system voltage, even though arcs on horizontally spaced lines approaching full system voltage have been reported. Consequently, a compromise condition was evaluated as shown by the current vector at 67 degrees leading, wherein the notation $LO = S90$ means that the line impedance at zero degrees (all arc) was taken numerically equal to the source impedance at 90 degrees and Z_D evaluated accordingly, giving due attention to the $\sqrt{3}$ and 2 factors. This would account for the arc absorbing somewhat more than half of the available voltage. Other intermediate vectors representing alternate conditions are occasionally used in other diagrams throughout these tables.

The method of analyzing the formulas is thus established as a study to determine what possible impedance values, both in

angle and in magnitude, can be utilized to yield the maximum angle and the minimum angle in either direction, and anything of a more reasonable nature as a limit in between.

As might be expected, the 2-phase-to-ground fault condition was more difficult to handle, both in derivation and analysis, than the other three combined. The only practical way which could be found was to introduce a factor A, a real or complex number, letting

$$A = \frac{Z_0}{Z_1} \tag{3}$$

in which Z_0 and Z_1 represents the final equivalent single impedances for the entire zero and positive sequence networks, respectively, as used in calculating the fault current components. The factor A is thus a ratio, and may vary from slightly more than zero to a very large number. In general, however, its possibilities were considered on the basis of it being either 0+ or 1. Large values of A make the 2-phase-to-ground fault approach the conditions of a phase-to-phase fault, as may be verified by comparing the formulas. (The one case where this does not hold true is for the 60°, number 2 connection, Figures 1 and 2, which received the necessary special attention.)

Typical of a case where A is taken at 0+, consider Relay B, line 3, Table V. The formula is

$$Z_D = \frac{\sqrt{3}AZ_{1S}\underline{/330^\circ} + (1+2A)Z_{1L}\underline{/300^\circ}}{1+A\underline{/60^\circ}} \tag{4}$$

Consider the limiting condition when the line impedance is zero so that the second term of the numerator drops out. Now assume that A is very small, and a real number (meaning that Z_0 and Z_1 have the same angle). The denominator is then practically unity and may be neglected. This leaves the angle to be determined by $Z_{1S}\underline{/330^\circ}$, and with a 90-degree source circuit, this yields 60 degrees for current lagging voltage. A current vector is accordingly shown at this angle in the vector diagram with the notation $S90$, $A=0+$.

It is of importance of note that the magnitude of Z_D, heretofore not discussed, is a measure of the ratio of the voltage to the current. If this ratio becomes low enough, the relay will not operate. The condition just discussed approaches this condition, where $A=0+$. An auxiliary condition was calculated for $A=1$, a real number, yielding an angle of 30 degrees lagging, which has been shown.

A value of $A=1$ can be obtained three ways. First, at zero line impedance, the ratio of source impedances can be unity.

Table VI. System Figure 2

CONNECTIONS	PHASES FAULTED	RELAY A	RELAY B	RELAY C
90°	A-G				BC-G			
60° #1	A-G		—		BC-G			
60° #2	A-G				BC-G			
30°	A-G				BC-G			

Secondly, if the line impedance is represented by a high value of arc resistance, A automatically becomes one. Such a condition forms the 90-degree current leading limit for the diagram under discussion. Thirdly, an assumption has been made that, for the sake of even figures, the zero sequence impedance of the line is equal to four times the positive sequence impedance, hence if the fault is appropriately located a sufficient distance down the line, A becomes unity, even with a low zero sequence source impedance.

Transferring attention to the diagram for Relay C, line 3, Table V, a new symbol $R\underline{/-67^\circ}$ is discovered. It represents the maximum angular rotating effect of -67 degrees which could be discovered by trial calculations for the portion $A/1+A\underline{/300^\circ}$ of the formula for this relay as applied to the Z_{1S} term with $Z_{1L}=0$ and in which A is a complex number occasioned by the existence of a resistance to ground in the fault affecting the zero sequence network only, as illustrated by R_g in Figure 6. The R factor appears again at different points in these tables representing the same type of operation with

angular values appropriate to the occasion. In all cases where the R factor was used, it was evaluated on the basis that the source impedances were at angles of 90 degrees lag and that $Z_{0S}=0.05Z_{1S}$. In the same vector diagram (Relay C, line 3, Table V) the factor A is used equal to 1 based on $Z_{0L}=4Z_{1L}$.

The 2-phase-to-ground fault condition is particularly tricky to handle for the 60°, number 2 connection by virtue of the fact that the fault condition in itself is complicated enough, and with the relay using phase-to-ground voltage for polarization, the analysis becomes tedious. In this case, the R_f value Figure 6 is likely to become quite important, as may be seen by the 150-degree angle shown for Relay C, Table V, line 11. This diagram also shows a case where it was desirable to consider values for A of 1, 4, and infinity.

Other symbolic notation used in these tables is explained as follows:

$L=0$ means that the line has no impedance, contrasting with the symbol LO described previously.

Z_{0S} denotes the zero sequence impedance in the source up to the relay, while Z_0 denotes the total zero sequence network.

Z_T represents the total of all impedances used in making the initial fault current calculation, as for example, in calculating a single-phase-to-ground fault $Z_T=Z_1+Z_2+Z_0$.

Z_{TR} represents the impedance of the transformer in Figure 3.

In preparing Table VII for Figure 3, it was necessary in some cases to assume a very low limit for the impedance of the transformer, but not zero. In such cases, it was assumed equal to 5 per cent of the positive sequence source impedance and is so indicated.

Summary of Results

The vector diagrams now may be studied in the light of directional element phase angle characteristics either as they are, or as they should be.

Considering the 90-degree connection first, it will be recalled that when this connection is used, the relay is usually equipped with phase shifting means to put the zero torque line at 45 degrees lagging—135 degrees leading, and the directional element therefore has maximum torque when the current leads the voltage by 45 degrees. A study of the vector diagrams reveals three cases where the current falls in the contact opening zone by being either more than 45 degrees lagging or more than 135 degrees leading. These

Figure 6. Location of fault resistance affecting zero sequence network only

are (1) Relay *B*, *BC-G* fault, System Figure 1; (2) Relay *C*, *A-G* fault, System Figure 2; and (3) Relay *B*, *YZ* fault, System Figure 3. The last two cases may be dismissed as nontroublesome on the basis that the conditions assumed for these limits are associated with such low current values that the fault detecting element can hardly be expected to operate. In case of doubt, the formulas may be used to investigate particular conditions short of the limits shown here. In the first case, however, a hazard of possible false operation does exist when the relay location is as shown in Figure 5 and with the fault back of the relay as in location 1 or 2. It will be remembered that for this location, a previous discussion gave the 60-degree, number 1 connection a preference for other reasons

The 60-degree, number 1 connection is generally used with an element having a watt-type characteristic, which means that the zero torque line falls at 90 degrees leading and lagging the reference voltage, with a maximum contact closing torque produced when the current and voltage are in phase. With this type of characteristic, the only possibilities of trouble are for Relay *A*, *BC* fault, System Figure 1, and for Relay *C*, *X-G* fault, System Figure 3. In each of these cases it is doubtful if the fault detecting element will receive enough current to operate.

In the case of the 60-degree, number 2 connection, if a watt-type element is used, the first possibility of trouble is encountered in connection with System Figure 1, *BC-G* fault, Relay *C*, for the condition of $R_g=0+$, $A=0+$, $L=0$, where an incorrect directional indication would obtain. This fault would be cleared by relay *B* acting alone. The problem of the incorrect indication of relay *C* causing a false trip out is, once again, limited to a location as shown by Figure 5. Other cases where the current leads the voltage by more than 90 degrees are discovered for System Figure 2, *A-G* fault, Relay *C*, and System Figure 3, *YZ* fault, Relay *B*. The possibility of causing a false trip out by approaching these limits depends on the magnitude of current involved as it affects the fault detecting element.

The 30-degree connection remains free of trouble only as long as the application is described by System Figure 1. If applied as shown by Figures 2 or 3, it is easily seen that erroneous directional indications will result with probable current magnitudes within the range of operation of the fault detecting element, thus leading to false tripping.

Conclusions

1. The general practice of shifting the angle of maximum torque to approximately 45 degrees leading for the 90-degree connection appears to give the best characteristic to fit the spread of possible phase angles.
2. A watt-type element appears to be best suited to the three remaining types of connections.
3. Each connection theoretically involves possibility of trouble in certain extreme cases.
4. The 30-degree connection is not suited to systems as shown by Figures 2 and 3.

General Notes on Derivation of Formulas

The following appendixes I, II, and III, cover the calculation of the necessary fault currents and voltages for the four types of faults, following which the Z_D formulas appropriate to the several relay connections are derived for enough cases to illustrate the method. The sequence network connections for the various fault calculations are not shown as it is taken for granted that those who check this work will be familiar with the method of symmetrical components.

The following remarks, however, are appropriate.

V_a' represents the generated voltage which causes the fault current to flow.

Subscripts 1, 2, and 0 denote positive, negative, and zero sequence, respectively, as applied to current, voltage, or impedance.

Subscripts *S* and *L* denote source and line, respectively.

Impedance symbols with 1, 2, or 0 subscripts only denote the total impedance of the respective positive, negative, or zero sequence network to the point of fault.

The relay voltages are calculated for the bus *G*.

A is the ratio Z_0/Z_1.

For simplicity, phase-to-ground voltages at bus *G* are written without the second subscript, V_a instead of V_{ag}.

$$V_b=a^2V_{a1}+aV_{a2}=\frac{V_a'}{Z_T}(a^2Z_{1S}+2a^2Z_{1L}+aZ_{1S})=\frac{V_a'}{Z_T}(Z_{1S}\underline{/180^\circ}+2Z_{1L}\underline{/240^\circ}) \tag{15}$$

$$V_c=aV_{a1}+a^2V_{a2}=\frac{V_a'}{Z_T}(aZ_{1S}+2aZ_{1L}+a^2Z_{1S})=\frac{V_a'}{Z_T}(Z_{1S}\underline{/180^\circ}+2Z_{1L}\underline{/120^\circ}) \tag{16}$$

$$V_{ab}=V_a-V_b=\frac{V_a'}{Z_T}(3Z_{1S}+2\sqrt{3}Z_{1L}\underline{/30^\circ}) \tag{17}$$

$$V_{bc}=V_b-V_c=\frac{V_a'}{Z_T}(2\sqrt{3}Z_{1L}\underline{/270^\circ}) \tag{18}$$

$$V_{ca}=V_c-V_a=\frac{V_a'}{Z_T}(3Z_{1S}\underline{/180^\circ}+2\sqrt{3}Z_{1L}\underline{/150^\circ}) \tag{19}$$

Derive the Z_D formulas

90° Connection

$$\text{Relay A: } Z_D=\frac{V_{bc}}{I_a}=\infty \text{ (no current)} \tag{20}$$

Relay B: $Z_D = \frac{V_{ca}}{I_b} =$

$$\frac{3Z_{1S}\angle 180^\circ + 2\sqrt{3}Z_{1L}\angle 150^\circ}{\sqrt{3}\angle 270^\circ} \times \frac{\angle 90^\circ}{\angle 90^\circ}$$

The term V_a'/Z_T is not shown because it appears in both numerator and denominator and therefore cancels out. The multiplication by $\angle 90^\circ/\angle 90^\circ$ is to convert the denominator to a real term.

$$Z_D = \sqrt{3}Z_{1S}\angle 270^\circ + 2Z_{1L}\angle 240^\circ \tag{21}$$

Relay C: $Z_D = \frac{V_{ab}}{I_c} =$

$$\frac{3Z_{1S} + 2\sqrt{3}Z_{1L}\angle 30^\circ}{\sqrt{3}\angle 90^\circ} \times \frac{\angle 270^\circ}{\angle 270^\circ}$$

$$= \sqrt{3}Z_{1S}\angle 270^\circ + 2Z_{1L}\angle 300^\circ \tag{22}$$

60° Connection
Number 1

Relay A: $Z_D = \frac{V_{ac}}{I_a - I_b} = \frac{-V_{ca}}{I_a - I_b} =$

$$\frac{3Z_{1S} + 2\sqrt{3}Z_{1L}\angle 330^\circ}{\sqrt{3}\angle 90^\circ} \times \frac{\angle 270^\circ}{\angle 270^\circ}$$

$$= \sqrt{3}Z_{1S}\angle 270^\circ + 2Z_{1L}\angle 240^\circ \tag{23}$$

Relay B: $Z_D = \frac{V_{bc}}{I_b - I_c} \quad \frac{-V_{ab}}{I_b - I_c} =$

$$\frac{3Z_{1S}\angle 180^\circ + 2\sqrt{3}Z_{1L}\angle 210^\circ}{2\sqrt{3}\angle 270^\circ} \times \frac{\angle 90^\circ}{\angle 90^\circ}$$

$$= \frac{\sqrt{3}}{2}Z_{1S}\angle 270^\circ + 2Z_{1L}\angle 300^\circ \tag{24}$$

Relay C: $Z_D = \frac{V_{cb}}{I_c - I_a} = \frac{-V_{bc}}{I_c - I_a} =$

$$\frac{2\sqrt{3}Z_{1L}\angle 90^\circ}{\sqrt{3}\angle 90^\circ} = 2Z_{1L} \tag{25}$$

60° Connection
Number 2

Relay A: $Z_D = \frac{-V_c}{I_a} = \infty$ (26)

Relay B: $Z_D = \frac{-V_a}{I_b} =$

$$\frac{2Z_{1S}\angle 180^\circ + 2Z_{1L}\angle 180^\circ}{\sqrt{3}\angle 270^\circ} \times \frac{\angle 90^\circ}{\angle 90^\circ}$$

$$= \frac{2}{\sqrt{3}}(Z_{1S}\angle 270^\circ + Z_{1L}\angle 270^\circ) \tag{27}$$

Relay C: $Z_D = \frac{-V_b}{I_c} =$

$$\frac{Z_{1S} + 2Z_{1L}\angle 60^\circ}{\sqrt{3}\angle 90^\circ} \times \frac{\angle 270^\circ}{\angle 270^\circ}$$

$$= \frac{1}{\sqrt{3}}(Z_{1S}\angle 270^\circ + 2Z_{1L}\angle 330^\circ) \tag{28}$$

30° Connection

Relay A: $Z_D = \frac{V_{ac}}{I_a} = \infty$ (29)

Relay B: $Z_D = \frac{V_{ba}}{I_b}$

$$= \frac{3Z_{1S}\angle 180^\circ + 2\sqrt{3}Z_{1L}\angle 210^\circ}{\sqrt{3}\angle 270^\circ} \times \frac{\angle 90^\circ}{\angle 90^\circ}$$

$$= \sqrt{3}Z_{1S}\angle 270^\circ + 2Z_{1L}\angle 300^\circ \tag{30}$$

Relay C: $Z_D = \frac{V_{cb}}{I_c} = \frac{2\sqrt{3}Z_{1L}\angle 90^\circ}{\sqrt{3}\angle 90^\circ} = 2Z_{1L}$ (31)

Phase A-to-Ground Fault

Calculate currents, and voltages at bus G

$$I_{a1} = I_{a2} = I_{a0} = \frac{V_a'}{Z_1 + Z_2 + Z_0} = \frac{V_a'}{Z_T} \tag{32}$$

$$I_a = 3I_{a1} = 3\frac{V_a'}{Z_T} \tag{33}$$

$$I_b = I_c = 0 \tag{34}$$

$$I_a - I_b = 3\frac{V_a'}{Z_T} \tag{35}$$

$$I_b - I_c = 0 \tag{36}$$

$$I_c - I_a = 3\frac{V_a'}{Z_T}\angle 180^\circ \tag{37}$$

$$V_{a1} = V_a' - I_{a1}Z_{1S} = V_a' - \frac{V_a'}{Z_T}Z_{1S}$$

$$= \frac{V_a}{Z_T}(Z_T + Z_{1S}\angle 180^\circ) \tag{38}$$

$$V_{a2} = -I_{a2}Z_{2S} = \frac{V_a'}{Z_T}Z_{2S}\angle 180^\circ \tag{39}$$

$$V_{a0} = -I_{a0}Z_{0S} = \frac{V_a'}{Z_T}Z_{0S}\angle 180^\circ \tag{40}$$

$$V_a = V_{a1} + V_{a2} + V_{a0} =$$

$$\frac{V_a'}{Z_T}(Z_T + 2Z_{1S}\angle 180^\circ + Z_{0S}\angle 180^\circ) \tag{41}$$

But $Z_T = 2Z_{1S} + 2Z_{1L} + Z_{0S} + Z_{0L}$ (42)

$$V_a = \frac{V_a'}{Z_T}(2Z_{1L} + Z_{0L}) \tag{43}$$

$$V_b = a^2V_{a1} + aV_{a2} + V_{a0}$$

$$= \frac{V_a'}{Z_T}(Z_T\angle 240^\circ + Z_{1S}\angle 60^\circ + Z_{1S}\angle 300^\circ + Z_{0S}\angle 180^\circ)$$

$$= \frac{V_a'}{Z_T}(\sqrt{3}Z_{1S}\angle 270^\circ + \sqrt{3}Z_{0S}\angle 210^\circ + 2Z_{1L}\angle 240^\circ + Z_{0L}\angle 240^\circ) \tag{44}$$

$$V_c = aV_{a1} + a^2V_{a2} + V_{a0}$$

$$= \frac{V_a'}{Z_T}(Z_T\angle 120^\circ + Z_{1S}\angle 300^\circ + Z_{1S}\angle 60^\circ + Z_{0S}\angle 180^\circ)$$

$$= \frac{V_a'}{Z_T}(\sqrt{3}Z_{1S}\angle 90^\circ + \sqrt{3}Z_{0S}\angle 150^\circ + 2Z_{1L}\angle 120^\circ + Z_{0L}\angle 120^\circ) \tag{45}$$

The phase-to-phase voltages are derived as in a preceding section by taking the difference between the appropriate phase-to-ground voltages, above. Substitutions are made within the parenthesis for Z_T in accordance with equation 42 in order to separate the source and line impedance terms so that the end results are:

$$V_{ab} = \frac{V_a'}{Z_T}(\sqrt{3}Z_{1S}\angle 90^\circ + \sqrt{3}Z_{0S}\angle 30^\circ + 2\sqrt{3}Z_{1L}\angle 30^\circ + \sqrt{3}Z_{0L}\angle 30^\circ) \tag{46}$$

$$V_{bc} = \frac{V_a'}{Z_T}(2\sqrt{3}Z_{1S}\angle 270^\circ + \sqrt{3}Z_{0S}\angle 270^\circ + 2\sqrt{3}Z_{1L}\angle 270^\circ + \sqrt{3}Z_{0L}\angle 270^\circ) \tag{47}$$

$$V_{ca} = \frac{V_a'}{Z_T}(\sqrt{3}Z_{1S}\angle 90^\circ + \sqrt{3}Z_{0S}\angle 150^\circ + 2\sqrt{3}Z_{1L}\angle 150^\circ + \sqrt{3}Z_{0L}\angle 150^\circ) \tag{48}$$

The relay formulas are derived in the same manner as in a preceding section. The expression for current in each case is so simple that performing the necessary division of current into voltage is done in one step, yielding at once the formulas which are already tabulated in Table I for phase-A-to-ground fault, hence there is no point in repeating them here.

Two-Phase-to-Ground Fault on Phases B and C

The sequence networks are, of course, connected in parallel, and from this consideration

$$Z_T = Z_1 + \frac{Z_2Z_0}{Z_2 + Z_0}$$

Letting

$$A = \frac{Z_0}{Z_1} \tag{49}$$

and since $Z_1 = Z_2$ is assumed

$$Z_T = Z_1\left(\frac{1+2A}{1+A}\right) \tag{50}$$

Calculate the currents, and voltages at bus G

$$I_{a1} = \frac{V_a'}{Z_T}$$

$$I_{a2} = -I_{a1}\frac{Z_0}{Z_2 + Z_0} = -I_{a1}\frac{AZ_1}{Z_1(1+A)} = \frac{A}{1+A} \times I_{a1}\angle 180^\circ \tag{51}$$

$$I_{a0} = -I_{a1}\frac{Z_2}{Z_2 + Z_0} = -I_{a1}\frac{Z_1}{Z_1(1+A)}$$

$$= \frac{1}{1+A}I_{a1}\angle 180^\circ \tag{52}$$

$$I_a = I_{a1} + I_{a2} + I_{a0} = 0 \tag{53}$$

$$I_b = a^2I_{a1} + aI_{a2} + I_{a0} =$$

$$I_{a1}\left(\angle 240^\circ + \frac{A}{1+A}\angle 300^\circ + \frac{1}{1+A}\angle 180^\circ\right)$$

$$= \frac{V_a'}{Z_T(1+A)}(\sqrt{3}\angle 210^\circ + \sqrt{3}A\angle 270^\circ) \tag{54}$$

Similarly,

$$I_c=\frac{V_a'}{Z_T(1+A)}(\sqrt{3}\underline{/150^\circ}+\sqrt{3}A\underline{/90^\circ}) \quad (55)$$

$$I_a-I_b=\frac{V_a'}{Z_T(1+A)}(\sqrt{3}\underline{/30^\circ}+\sqrt{3}A\underline{/90^\circ}) \quad (56)$$

$$I_b-I_c=\frac{V_a'}{Z_T(1+A)}(\sqrt{3}\underline{/270^\circ}+2\sqrt{3}A\underline{/270^\circ}) \quad (57)$$

$$I_c-I_a=\frac{V_a'}{Z_T(1+A)}(\sqrt{3}\underline{/150^\circ}+\sqrt{3}A\underline{/90^\circ}) \quad (58)$$

$$V_{a1}=V_a'-I_{a1}Z_{1S}=V_a'-\frac{V_a'}{Z_T}Z_{1S}$$

$$=\frac{V_a'}{Z_T}(Z_T-Z_{1S}) \quad (59)$$

$$V_{a2}=-I_{a2}Z_{1S}=\frac{A}{1+A}I_{a1}Z_{1S}$$

$$=\frac{V_a'}{Z_T}\left(\frac{A}{1+A}Z_{1S}\right) \quad (60)$$

$$V_{a0}=-I_{a0}Z_{0S}=\frac{1}{1+A}I_{a1}Z_{0S}$$

$$=\frac{V_a'}{Z_T}\left(\frac{1}{1+A}Z_{0S}\right) \quad (61)$$

$$V_a=V_{a1}+V_{a2}+V_{a0}$$

$$=\frac{V_a'}{Z_T}\left(Z_T+Z_{1S}\left(-1+\frac{A}{1+A}\right)+\frac{Z_{0S}}{1+A}\right)$$

$$=\frac{V_a'}{Z_T(1+A)}(2AZ_{1S}+Z_{0S}+Z_{1L}(1+2A)) \quad (62)$$

$$V_b=a^2V_{a1}+aV_{a2}+V_{a0}=$$

$$\frac{V_a'}{Z_T}\left((Z_T-Z_{1S})a^2+\frac{A}{1+A}aZ_{1S}+\frac{1}{1+A}Z_{0S}\right)$$

$$=\frac{Va'}{Z_T(1+A)}(AZ_{1S}\underline{/180^\circ}+Z_{0S}+(1+2A)Z_{1L}\underline{/240^\circ}) \quad (63)$$

$$V=aV_{a1}+a^2V_{a2}+V_{a0}$$

$$=\frac{V_a'}{Z_T}\left((Z_T-Z_{1S})a+\frac{A}{1+A}a^2Z_{1S}+\frac{Z_{0S}}{1+A}\right)$$

$$=\frac{V_a'}{Z_T(1+A)}(AZ_{1S}\underline{/180^\circ}+Z_{0S}+(1+2A)Z_{1L}\underline{/120^\circ}) \quad (64)$$

The phase-to-phase voltages are derived as before, and separating source and line impedances, they are found to be

$$V_{ab}=\frac{V_a'}{Z_T(1+A)}(3AZ_{1S}+\sqrt{3}(1+2A)Z_{1L}\times\underline{/30^\circ}) \quad (65)$$

$$V_{bc}=\frac{V_a'}{Z_T(1+A)}(\sqrt{3}(1+2A)Z_{1L}\underline{/270^\circ}) \quad (66)$$

$$V_{ca}=\frac{V_a'}{Z_T(1+A)}(3AZ_{1S}\underline{/180^\circ}+\sqrt{3}(1+2A)\times Z_{1L}\underline{/150^\circ}) \quad (67)$$

With the expressions of voltage and current now available, the relay formulas are derived in a manner similar to those in the two preceding sections. The algebra of the operations is a bit more complicated in this case, however, because of the greater complexity of the current expressions, hence the derivations will be given here for the "90° Connection," to illustrate the method.

90° Connection

Relay A: $Z_D=\frac{V_{bc}}{I_a}=\infty$ (68)

Relay B: $Z_D=\frac{V_{ca}}{I_b}=$

$$\frac{3AZ_{1S}\underline{/180^\circ}+\sqrt{3}(1+2A)Z_{1L}\underline{/150^\circ}}{\sqrt{3}\underline{/210^\circ}+\sqrt{3}A\underline{/270^\circ}} \quad (69)$$

There are two different angular operators in the denominator so that it is impossible to reduce each of them to a real number in the same way that the denominators in previous illustrations were reduced. The best that can be done is to reduce one of the factors to a real term, and the factor chosen is the one not involving A. Inspection shows that if an angle of 150° is added, this will be done, hence multiply both numerator and denominator by $\underline{/150^\circ}$, and cancel out $\sqrt{3}$ from each.

$$Z_D=\frac{\sqrt{3}AZ_{1S}\underline{/330^\circ}+(1+2A)Z_{1L}\underline{/300^\circ}}{1+A\underline{/60^\circ}} \quad (70)$$

Relay C: Z_D

$$=\frac{3AZ_{1S}+\sqrt{3}(1+2A)Z_{1L}\underline{/30^\circ}}{\sqrt{3}\underline{/150^\circ}+\sqrt{3}A\underline{/90^\circ}}\times\frac{\underline{/210^\circ}}{\underline{/210^\circ}}$$

$$=\frac{\sqrt{3}AZ_{1S}\underline{/210^\circ}+(1+2A)Z_{1L}\underline{/240^\circ}}{1+A\underline{/300^\circ}} \quad (71)$$

Utilizing the above method of derivation yields the formulas for the remaining relay connections, and these are listed in Table I.

Three-Phase Fault

Calculate the currents, and voltages at bus G

$$I_{a1}=\frac{V_a'}{Z_{1S}+Z_{1L}}=\frac{V_a'}{Z_T} \quad (72)$$

$$I_{a2}=I_{a0}=0 \quad (73)$$

$$I_a=I_{a1}=\frac{V_a'}{Z_T} \quad (74)$$

$$I_b=a^2I_{a1}=a^2\frac{V_a'}{Z_T} \quad (75)$$

$$I_c=aI_{a1}=a\frac{V_a'}{Z_T} \quad (76)$$

$$I_a-I_b=\sqrt{3}\frac{V_a'}{Z_T}\underline{/30^\circ} \quad (77)$$

$$I_b-I_c=\sqrt{3}\frac{V_a'}{Z_T}\underline{/270^\circ} \quad (78)$$

$$I_c-I_a=\sqrt{3}\frac{V_a'}{Z_T}\underline{/150^\circ} \quad (79)$$

$$V_a=I_{a1}Z_{1L}=\frac{V_a'}{Z_T}Z_{1L} \quad (80)$$

$$V_b=a^2V_a=\frac{V_a'}{Z_T}Z_{1L}\underline{/240^\circ} \quad (81)$$

$$V_c=aV_a=\frac{V_a'}{Z_T}Z_{1L}\underline{/120^\circ} \quad (82)$$

$$V_{ab}=V_a-V_b=\sqrt{3}\frac{V_a'}{Z_T}Z_{1L}\underline{/30^\circ} \quad (83)$$

$$V_{bc}=V_b-V_c=\sqrt{3}\frac{V_a'}{Z_T}Z_{1L}\underline{/270^\circ} \quad (84)$$

$$V_{ca}=V_c-V_a=\sqrt{3}\frac{V_a'}{Z_T}Z_{1L}\underline{/150^\circ} \quad (85)$$

Because of the symmetry of the 3-phase fault, only one relay formula is needed per connection. These are derived as before, and are listed in Table I.

Appendix II. System Figure 2

Inasmuch as Appendix I has shown the method of derivation of the Z_D formulas for the relay directional elements as well as the method of deriving the currents and voltages this appendix will merely list for reference the currents and voltages involved. This will only be necessary for faults involving ground, because for phase-to-phase and 3-phase faults, Figure 2 is a duplicate of Figure 1. The Z_D formulas are given in Table II.

Phase-A-to-Ground Fault

$$Z_T=Z_1+Z_2+Z_0=2Z_1+Z_0 \quad (86)$$

$$I_{a1}=I_{a2}=I_{a0}=\frac{V_a'}{Z_T} \quad (87)$$

$$I_a=2\frac{V_a'}{Z_T} \quad (88)$$

$$I_b=\frac{V_a'}{Z_T}\underline{/180^\circ} \quad (89)$$

$$I_c=\frac{V_a'}{Z_T}\underline{/180^\circ} \quad (90)$$

$$I_a-I_b=3\frac{V_a'}{Z_T} \quad (91)$$

$$I_b-I_c=0 \quad (92)$$

$$I_c-I_a=3\frac{V_a'}{Z_T}\underline{/180^\circ} \quad (93)$$

$$V_{a1}=\frac{V_a'}{Z_T}(Z_T+Z_{1S}\underline{/180^\circ}) \quad (94)$$

$$V_{a2}=\frac{V_a'}{Z_T}Z_{1S}\underline{/180^\circ} \quad (95)$$

$$V_{a0}=\frac{V_a'}{Z_T}Z_0\underline{/180^\circ} \quad (96)$$

$$V_a=\frac{V_a'}{Z_T}2Z_{1L} \quad (97)$$

$$V_b=\frac{V_a'}{Z_T}(\sqrt{3}Z_{1S}\underline{/270^\circ}+\sqrt{3}Z_0\underline{/210^\circ}+2Z_{1L}\underline{/240^\circ}) \quad (98)$$

$$V_c=\frac{V_a'}{Z_T}(\sqrt{3}Z_{1S}\underline{/90^\circ}+\sqrt{3}Z_0\underline{/150^\circ}+2Z_{1L}\underline{/120^\circ} \quad (99)$$

$$V_{ab}=\frac{V_a'}{Z_T}(\sqrt{3}Z_{1S}\underline{/90^\circ}+\sqrt{3}Z_0\underline{/30^\circ}+2\sqrt{3}Z_{1L}\underline{/30^\circ}) \quad (100)$$

$$V_{bc}=\frac{V_a'}{Z_T}(2\sqrt{3}Z_{1S}\underline{/270^\circ}+\sqrt{3}Z_0\underline{/270^\circ}+2\sqrt{3}Z_{1L}\underline{/270^\circ}) \quad (101)$$

$$V_{ca}=\frac{V_a'}{Z_T}(\sqrt{3}Z_{1S}\underline{/90^\circ}+\sqrt{3}Z_0\underline{/150^\circ}+2\sqrt{3}Z_{1L}\underline{/150^\circ}) \quad (102)$$

Two-Phase-to-Ground Fault on Phases B and C

$$Z_T=Z_1+\frac{Z_0Z_2}{Z_0+Z_2}=Z_1\frac{1+2A}{1+A} \quad (103)$$

$$A=\frac{Z_0}{Z_1} \text{ and } Z_1=Z_2 \quad (104)$$

$$I_{a1}=\frac{V_a'}{Z_T} \quad (105)$$

$$I_{a2}=\frac{A}{1+A}\frac{V_a'}{Z_T}\underline{/180^\circ} \quad (106)$$

$$I_{a0}=\frac{1}{1+A}\frac{V_a'}{Z_T}\underline{/180^\circ} \quad (107)$$

Currents at relay location, bus G, do not involve zero sequence.

Therefore

$$I_a=I_{a1}+I_{a2}=\frac{V_a'}{Z_T}\frac{1}{1+A} \quad (108)$$

$$I_b=\frac{V_a'}{Z_T}\frac{1}{1+A}(1\underline{/240^\circ}+\sqrt{3}A\underline{/270^\circ}) \quad (109)$$

$$I_c=\frac{V_a'}{Z_T}\frac{1}{1+A}(1\underline{/120^\circ}+\sqrt{3}A\underline{/90^\circ}) \quad (110)$$

$$I_a-I_b=\frac{Va'}{Z_T\ (1+A)}(\sqrt{3}\underline{/30^\circ}+\sqrt{3}A\underline{/90^\circ}) \quad (111)$$

$$I_b-I_c=\frac{V_a'}{Z_T\ (1+A)}(\sqrt{3}\underline{/270^\circ}+2\sqrt{3}A\underline{/270^\circ}) \quad (112)$$

$$I_c-I_a=\frac{Va'}{Z_T(1+A)}(\sqrt{3}\underline{/150^\circ}+\sqrt{3}A\underline{/90^\circ}) \quad (113)$$

$$V_{a1}=\frac{V_a'}{Z_T}(Z_T-Z_{1S}) \quad (114)$$

$$V_{a2}=\frac{A}{1+A}\frac{V_a'}{Z_T}Z_{1S} \quad (115)$$

$$V_{a0}=\frac{1}{1+A}\frac{V_a'}{Z_T}Z_0=\frac{A}{1+A}\frac{V_a'}{Z_T}Z_1 \quad (116)$$

$$V_a=\frac{Va'}{Z_T(1+A)}(3AZ_{1S}+Z_{1L}(1+3A)) \quad (117)$$

$$V_b=\frac{V_a'}{Z_T(1+A)}(Z_{1L}(1\underline{/240^\circ}+\sqrt{3}A\underline{/270^\circ})) \quad (118)$$

$$V_c=\frac{V_a'}{Z_T(1+A)}(Z_{1L}(1\underline{/120^\circ}+\sqrt{3}A\underline{/90^\circ})) \quad (119)$$

$$V_{ab}=\frac{V_a'}{Z_T(1+A)}(3AZ_{1S}+\sqrt{3}(1+2A)Z_{1L}\underline{/30^\circ}) \quad (120)$$

$$V_{bc}=\frac{V_a'}{Z_T(1+A)}(\sqrt{3}(1+2A)Z_{1L}\underline{/270^\circ}) \quad (121)$$

$$V_{ca}=\frac{V_a'}{Z_T(1+A)}(3AZ_{1S}\underline{/180^\circ}+\sqrt{3}(1+2A)Z_{1L}\underline{/150^\circ}) \quad (122)$$

Appendix III. System Figure 3

In this case, a delta star connected transformer bank is interposed between the relay location and the fault. The phase relationships assumed are that the star side voltages x, y, z, (high voltage assumed) are 30° leading the delta voltages a, b, c (low voltage assumed). Calculations are made initially from the star connected side, but it must be remembered that in passing through the transformer bank to the relay location, the positive sequence currents and voltages are rotated 30° lagging, the similar negative sequence components are rotated 30° leading, and the zero sequence current and voltage disappear.

In line with the policy established in Appendix II, only the expressions for the necessary currents and voltages will be shown here, remembering that the Z_D formulas are given in Table 3. Also, V_x' is used for the source voltage in this case rather than V_a' because of the different phase terminology used to identify the side of the transformer bank away from the relay.

Phase-to-Phase Fault on Phases YZ

$$Z_1=Z_{1S}+Z_{1TR}+Z_{1L}=Z_2 \quad (123)$$

$$Z_T=Z_1+Z_2=2Z_1 \quad (124)$$

$$I_{a1}=\frac{V_x'}{2Z_1}\underline{/330^\circ} \quad (125)$$

$$I_{a2}=\frac{V_x'}{2Z_1}\underline{/210^\circ} \quad (126)$$

$$I_a=\frac{V_x'}{2Z_1}\underline{/270^\circ} \quad (127)$$

$$I_b=\frac{V_x'}{2Z_1}\underline{/270^\circ} \quad (128)$$

$$V_{bc} = V_b - V_c = \frac{V_x'}{Z_1} (Z_{1TR} + Z_{1L})\sqrt{3}\underline{/240^\circ} \quad (192)$$

No other voltages are needed.

Discussion

Myron A. Bostwick (Portland General Electric Company, Portland, Oreg.): I wish to compliment Mr. Sonnemann for his excellent analysis of single-phase directional element connections. He has used a simple, readily understood approach to the problem, and provides more definite limits for successful operation than have been published previously. A glance at the many pages of calculations provides an indication of the thoroughness of his investigation.

Fortunately it is not necessary to dig through these voluminous calculations to use the information that has been provided. The vector diagrams tell the whole story, when considered in terms of the particular relay characteristics and connections. It also is essential to consider details of the power circuit as Mr. Sonnemann has indicated.

The need of this is emphasized by consideration of the diagrams, as described in the section on Summary of Results. The author has indicated that there are "three cases where the current falls in the contact opening zone by being either more than 45 degrees lagging or more than 135 degrees leading." He then discusses three conditions that may cause undesirable operation. In this discussion he fails to mention two conditions (the *B* relay, 90-degree connection, for a phase A-to-ground fault on system Figure 2, in table VI and the phase *A* relay, 90-degree connection, in Table VII for a *Y-Z* fault in system Figure 3) that also cause contact opening torque. Discussion of these was apparently omitted because the relays will not trip incorrectly on the reversed flow of current to an external fault. I think it desirable to have consideration of these relays included in the discussion for future reference and suggest that it be added to the paper.

The analysis has clinched my opinion that the 90-degree connection should be used generally in all applications, except those noted as being subject to incorrect operation. Individual study of those installations may then be required. In closing these remarks, I wish to thank Mr. Sonnemann for his clear analysis of the problem, and the tremendous amount of work that was required to present it.

W. K. Sonnemann: Mr. Bostwick has picked out two conditions which should have been discussed in the original paper. In the fourth paragraph preceding the "Conclusions," the reference should be to five cases where the current falls in the contact opening zone rather than just three. As a matter of fact, all of the vector diagrams were studied individually for their implications at the time of their original derivation, including these two. At the time of sifting and sorting all of the work which had been done in order to prepare the paper, however, these two were missed. The author regrets that they were missed, and thanks Mr Bostwick for calling attention to them.

In the first case, relay *B*, 90-degree connection, phase-*A*-to-ground fault, system Figure 2, there is the possibility of incorrect tripout for relays located at certain other points than that illustrated in Figure 2. For example, relays in the source circuit at bus *G*, as well as relays on the left-hand side of any bus interposed between the bus *G* and the fault, will "see" the vector relationships of Table VI line 1 in reverse, hence it is apparent that the possibility of erroneous tripout for relay *B* should be examined further. It is in cases such as this that it is well to bear in mind that the vector diagrams show extreme conditions which may be more theoretical than practical, and that an examination of the system constants may show the trouble to be nonexistent for a particular system. The formula for relay *B* under discussion is:

$$Z_D = \sqrt{3}[Z_{1S}\underline{/270^\circ} + (Z_0 + 2Z_{1L})\underline{/330^\circ}]$$

The limit condition of the current lagging by 60 degrees was obtained in this case by assuming that the zero sequence impedance is the governing factor through being large enough to make the other factors negligible, and that it has an angle of 90 degrees. The 90-degree angle is not too bad an assumption if the fault occurs at the far end of the line at the grounding bank location provided that the bank is not grounded through a resistor. If the fault is at the far end of the line, however, the impedance of the line is not necessarily negligible, and whether or not the source impedance is negligible by comparison depends upon the system. Assume, for example, that the line impedance is negligible, and take Z_0 at 1.00 $\underline{/90^\circ}$ for reference. If Z_{1S} is assumed at 90 degrees, it is found that it requires a scalar value of only 0.366 to bring the Z_D value to a 45-degree angle, the border line condition. Thus, if Z_{1S} exceeds 36.6 per cent of Z_0, the problem disappears for relays having a 45-degree characteristic. If Z_{1S} has a smaller angle than 90 degrees, a slightly greater

value will be required. If the transformer is grounded through a resistor, the characteristic angle of Z_0 approaches zero degrees, and the current approaches the 30-degree leading position.

The second case mentioned by Mr. Bostwick covering relay A, 90-degree connection, YZ fault, system Figure 3 is similar to the first in that relays in source circuits at bus G require scrutiny. The most severe condition occurs when the fault is right at the line terminals of the transformer so that Z_{1L}, assumed to have a smaller angle than 90 degrees, is zero. The angle of the transformer impedance Z_{1TR} is near 90 degrees, however, and dependence must be placed on the source impedance being relatively large in order to reduce the angle of Z_D to less than 45 degrees. If there are several source circuits connected to the bus, the condition will be materially aggravated for the relays on these source circuits by virtue of the multiplying effect of the current from the other sources on the apparent value of Z_{1TR} as seen, in reverse, by any one set of relays on a source circuit. It is conceivable that there will be systems wherein the 90-degree connection, with the 45-degree phase shifter, will be unsatisfactory. In such cases, the solution is to modify the 45-degree phase shifter if this does not cause trouble from one of the other limits, or else use one of the two 60-degree connections.

Local Wire Video Television Networks

C. N. NEBEL
NONMEMBER AIEE

A satisfactory local video distribution system is necessary to interconnect television studios, transmitters, and pick-up points within a city and to connect them to the coaxial cable and microwave intercity television networks.[1,2] Wire extension circuits also are necessary to distribute video signals from local microwave circuits which are used to pick up remote program material. This is necessary because space on a broadcaster's premise is often unavailable and undesirable from a system maintenance point of view for the operation of remote microwave equipments. A local video distribution system has been developed for the Bell Telephone System utilizing existing telephone facilities as much as practicable. Backbone routes in local areas use newly developed low loss shielded video cable pairs. In many cases these are supplemented by end links of existing paper pair cables.

Equipment is provided for the equalization and amplification of the video signals transmitted over wire circuits. This equipment consists of a transmitting terminal, an intermediate repeater with cable equalizers, and a receiving terminal. Video repeating coils (line transformers) are sometimes used at the terminals for direct connections to the cable pairs. A clamper also is used at the receiving terminal as a stabilizing element for low-frequency circuit noise and for restoring the low-frequency signal components which are removed by the terminal repeating coils.

The intermediate repeater contains four blocks of gain in the form of input and output amplifiers and two amplifier gain networks. The equalization for the cable loss is obtained by utilizing the gain-frequency characteristics of the two amplifier gain networks and of the equalizers which are connected between the two amplifiers. The equalization and gain is distributed throughout the system so as to obtain a reduction in cable and amplifier noise. Increased high-frequency noise suppression is obtained by means of signal predistortion, that is by transmitting the low-level high-frequency signal components over the system at a higher than normal level and restoring them to normal level at the receiving end of the circuit.

It is the purpose of this paper to describe these video transmission facilities more fully and to show the results obtained with some typical circuit applications.

Characteristics of Cable Plant

The cable plant in the local exchange areas available for video transmission consists of coaxial cables, existing interoffice trunk and subscriber paper insulated cables, and shielded polyethylene string and tape insulated cables.

Coaxial Cables

The first 4-megacycle video transmission circuits were used for relatively short studio-transmitter connections. Special installations of 0.268-inch coaxial cables with specially designed equalizers were provided to care for these cases. These were very special cases where the 4-megacycle loss was less than 20 decibels requiring no intermediate gain in the cables. Although they were short circuits, they had the disadvantage that ground currents induced into the outer coaxial conductor by neighboring power circuits caused serious interference. Although it could be balanced out by special means on short circuits, it was found impracticable to employ long unbalanced coaxial circuits in a large video transmission plant. Balanced pair cables provide a natural balance of 75 decibels or more to these interfering power frequencies and are, therefore, much more suitable for use in the development of a large video plant facility.

Existing Cable Plant

A wide variety of balanced circuits are to be found in the existing plant in the form of paper-insulated interoffice trunks and subscriber cable pairs. These existing facilities were fairly extensively used in the initial stages of this video plant development. It will be interesting at this point to examine the limitations of these circuits for video transmission.

There are four principal sources of noise interference on balanced transmission circuits. First are the voltages induced between the line conductors and ground from neighboring power systems. These act upon unbalances between the line conductors and ground to produce components in the metallic circuit. Second are impulse-type noises arising from cross-induction from message-circuit pairs in the cable. These originate in the many switching operations occurring in

Figure 3. Change in attenuation of typical paper cables at video frequencies for a total seasonal temperature change of 26 degrees Fahrenheit

the message plant, for example from switchhooks, dialing, ringing, teletypewriter, and so forth. Third are disturbing components arising by induction from other video in the same cable. Fourth is the noise due to thermal agitation in the cable conductors and shot noise in the vacuum tubes, usually referred to as amplifier input noise.

In general, protection from the first three types of noise is obtained by cable pair balance. A certain amount of impulse noise and amplifier input noise reduction is obtainable by pre-equalization and predistortion of the signal. Otherwise, increased shielding or separation of circuits must be provided to further reduce both impulse noise and video circuit crosstalk. Amplifier input noise at present is not limiting since it is kept to within about 15 decibels of the irreducible minimum which is cable thermal noise. The maximum repeater spacing is determined by one or more of these factors, that is, the repeater spacing or line loss may be increased until the signal becomes so small that a certain margin or difference exists between the signal level and the noise level. This level margin is the tolerable or acceptable viewing signal-to-noise ratio.

In the case of paper pair circuits, impulse noise limits the maximum repeater spacings to a 4-megacycle line loss of approximately 65 decibels with signal predistortion. When the input and output circuits to a repeater are in the same cable, interaction crosstalk[3] around the repeater limits the 4-megacycle loss of the line preceding the repeater to approximately 40 decibels If the input and output circuits to the repeater are in different cables, interaction crosstalk loss is usually so high that it is not a limitation. If two circuits operate in opposite directions within a cable, near end crosstalk limits the maximum 4-megacycle loss in both circuits to 40 decibels. If two circuits operate in the same direction within a cable, far end crosstalk limits the maximum 4-megacycle loss in both circuits to approximately 40 decibels. It can readily be seen from Table I on cable attenuation that crosstalk in paper pair circuits results in either very short repeater spacings or limits the number of circuits to one per cable. The average office spacing even in such high-density areas as metropolitan New York exceeds 40 decibels for paper pair. An office spacing of even 65 decibel is often difficult to obtain where only the impulse noise limitation is controlling. In these cases recourse to interoffice repeater locations on private property is necessary.

Subscriber pairs are provided with bridged taps or multiple outlets at various locations along the length of the pairs to make them more useful or available for assignment purposes. The presence of these taps introduce reflections or echoes from their open ended condition when such subscriber circuits are used for video transmission. The effect of such a tap upon the transmission characteristic is illustrated in Figure 1. The only satisfactory way to avoid this tap distortion in the video band is to remove the taps from the line. Since most taps are located within lead cable splices in man-

Figure 2. Attenuation of typical paper pair cables at video frequencies

Figure 4. Resistance component of typical paper pair cable impedance

Figure 5. Newly developed shielded video cables for use in the telephone plant

holes, their removal results in considerable expense and lengthy operations in preparing a pair for video use.

There is a wide variety of paper pair circuits available in the telephone plant. The transmission characteristics of these circuits have a large bearing upon their usefulness for video transmission purposes.

The attenuation of representative paper pairs throughout the 4-megacycle video band is shown in Figure 2. The bulk of the available pairs is confined to smaller gauges of 19 to 26 where the 4-megacycle loss ranges from 53 to 95 per mile. With the limitation of about 65-decibel repeater spacings imposed by impulse noise the maximum repeater spacings are then 1.23 miles for 19 gauge, and 0.685 mile for the 26-gauge-per-cable sheath. Due to existing office spacings these repeater spacings would make necessary a large number of off premise or private property repeater locations. Also a large number of repeaters would be required for the longer circuits encountered. These longer circuits may be from 10 to 20 miles in length. In these cases seasonal temperature variations become important, necessitating frequent circuit re-equalization. Temperature measurements in underground cable ducts in lower New York City were made throughout 1948. They gave a seasonal range of 26 degrees Fahrenheit. Figure 3 gives the attenuation-temperature variation throughout the 4-megacycle band in decibels per mile for a seasonal change of 26 degrees Fahrenheit for paper pair circuits. It will be seen that the 4-megacycle seasonal loss change for the average 22 gauge pair is 34 decibels for a 10-mile circuit having a total 4-megacycle loss of 680 decibels. This circuit would probably have 13 repeaters each of which would have to be re-equalized at least monthly to minimize the temperature effect upon circuit attenuation.

A given paper pair circuit is usually a composite of the various gauges available between two repeaters. The characteristic impedance of the various gauges varies considerably from one to another. The impedance mismatch at the junction of unlike gauges and especially between the smaller gauges and the repeater termination creates reflection losses. These reflection losses depend upon the particular gauges involved making it difficult to predetermine the necessary equalizer shapes to use. The resistance component of the characteristic impedance $(R+JX)$ of some paper pairs is given in Figure 4.

All of the enumerated characteristics of paper pair cables militate against their widespread use in a large and complex video plant. A more stable and lower cable loss is needed for the backbone circuits including broadcaster terminal and studio-transmitter circuits. The paper pair cables are then used mainly for short radial pickup circuit connections to the backbone route.

Shielded Video Cable Pairs

A new video cable pair has been developed to meet the demands of the backbone circuits. The high-frequency loss has been kept low by the use of large conductors and polyethylene insulation. The impulse noise and crosstalk have been

Figure 6. Attenuation of newly developed shielded video cables for use in the telephone plant

Figure 7. Impedance of newly developed shielded video cables for use in the telephone plant

Figure 8. Transmitting terminal of the *A2* video transmission system

reduced by shielding the balanced pairs. It is known as number 16 *PSV* (polyethylene shielded video). As shown in Figure 5 each number 16 American Wire Gauge copper conductor is insulated with a spirally wound polyethylene string and tape. Two spirally-wound 3-mil copper tapes with opposite lay are then placed around a pair of the insulated conductors to form the shielded pair. The 16 *PSV* shielded pairs are then placed in their own lead sheath or in with other paper pairs in large interoffice trunk cables. The average near end 4-megacycle crosstalk loss between the shielded pairs installed in this manner is about 120 decibels.

A modified design now is being produced. The inner shield is a 3-mil longitudinal seam copper tape with one 3-mil outside spiral tape. The new design has 1-decibel lower attenuation and about 25-decibel lower crosstalk at 4 megacycle. The impulse noise also is expected to be considerably lower on the new design.

Another cable known as *754C* also is shown in Figure 5 and has been provided for wiring within an office, for quick installations, or when only one or a small number of low loss circuits are required, usually from an office to a broadcaster. This cable uses solid polyethylene insulation covered with a double-braided copper shield with an outside jacket of grey polyvinyl chloride. The near end 4-megacycle crosstalk loss between two adjacent *754C* shielded cables is approximately 150 decibels. It is moisture resistant and may be pulled into underground cable ducts.

Representative attenuation and impedance characteristics of the shielded video pairs are given in Figures 6 and 7. The 4-megacycle loss of the number 16 *PSV* spiral shield and longitudinal shield cable is seen to be 18 decibels and 17 decibels per mile respectively. The attenuation-temperature change for a seasonal temperature range of 26 degrees Fahrenheit is given by the lower curve on Figure 3. It is seen to be 0.45 decibel per mile which is 13 per cent of that for 22-gauge paper pair.

As indicated previously, the near end 4-megacycle crosstalk is respectively 120 decibels and 145 decibels for the spiral and longitudinal shield cables and 150 decibels for the *754C* cable. Experience to date indicates that for the average crosstalk of 120 decibels from the spiral shield cable, 10 tandem repeater links of about 85 decibels each at 4 megacycles should result in substantially no impairment in picture quality due to crosstalk and office impulse noise. This assumes that the gain and equalization in each repeater is sufficient to make up for the preceding length of cable. However, office spacings and especially repeater spacings of such great lengths and numbers are not expected to occur frequently. Therefore, it should be satisfactory to operate occasional repeater spacings of 5 to 10 decibels longer if repeaters are provided with sufficient gain, equalization, and shielding for the purpose. An example of a 90-decibel repeater section is discussed in the special *A2* repeater application illustrated in Figure 22.

A2 Video Transmission System

The *A2* system at the present time is made up of a transmitting and receiving terminal and the necessary number of intermediate repeaters for the length of the

Figure 9. Standard transmitting terminal arrangement of Figure 8(A) in a wall mounted bracket

Figure 10. Loss characteristics of predistorter and restorer networks used for noise protection

Figure 11. Transmission characteristics of video repeating coils (line transformers)

cable circuit in use. The line equalization and most of the circuit gain is furnished by the repeater except in special cases.

Transmitting Terminal

The transmitting terminal arrangements are shown in Figure 8. It is common practice to use the repeating coil arrangement in Figure 8(A) to avoid the operation of the off premise transmitting amplifier in Figure 8(B). Figure 9 shows a standard transmitting terminal in a wall mounted cabinet. It has been normal practice for the broadcaster to deliver a 2-volt peak-to-peak signal from a 75-ohm unbalanced generator impedance to the transmitting terminal. The predistorter is used as shown if noise protection is needed in the circuit due to one or more long repeater links. The predistorter is an unbalanced 75 ohm constant resistance equalizer having the characteristic shown in Figure 10. The low-frequency loss below 1 megacycle is 20 decibels. This loss is great enough to isolate the customer's line monitor jacks from any impedance irregularity which may exist due to the repeating coil or the video cable pair. The predistorter is connected to the video cable pair with the 75: 110-ohm repeating coil as shown. The monitor jacks at the repeating coil output are for continuity monitoring.

The frequency characteristics of the *197A* and *197B* repeating coils are shown in Figure 11. The *197B* is a later design with a low-frequency cut off at 10 cycles per second The use of repeating coils

which remove the d-c and other low-frequency signal components is permissible if these signal components are reconstructed at the receiving end. The low-frequency components are restored by the clamper in the receiving terminal and the direct current is restored at the receiving tube.

In special cases the repeating coil may be replaced by an output amplifier as shown in Figure 8(B) having an unbalanced input impedance of 75 ohms and a balanced output impedance of 110 ohms. The maximum voltage gain is 30 decibels which is adjustable from 20 to 30 decibels in 2-decibel steps. The normal output operating level is 2 volts (peak to peak) which may be increased 3 decibels for a maximum of three output amplifiers in a circuit.

When a predistorter is used, its loss must be made up by 20 decibels of gain to give the desired increase in the high-frequency signal components. This gain is furnished by the first repeater when a repeating coil is used in the transmitting terminal. This limits the length of the first repeater link to a maximum of 30 decibels or 1.7 miles of number 16 *PSV*.

A special case exists when the distance to the first repeater office is greater than 1.7 miles. In this case an output amplifier is used to provide the gain for the predistorter and the output network. A maximum loss of 63 decibels or 3.5 miles to the first office repeater then is permissible.

Receiving Terminal

The receiving terminal arrangements are shown in Figure 12. It is common practice to use the arrangement in Figure 12(A), when the length of the preceding line is not greater than 27 decibels. Figure 13 shows a standard receiving terminal in a wall mounted cabinet. A repeating coil is used to connect the balanced cable pair to the 75-ohm unbalanced circuits. The restorer is used ahead of the clamper as shown when the signal has been predistorted at the transmitting terminal. The clamper amplifier has a maximum gain of 18 decibels, adjustable in steps of 1 decibel. The signal delivered to the customer's 75-ohm load impedance is 2

Figure 16 (left). An installation of intermediate repeaters in a telephone office

Figure 18 (above). Characteristics of cable equalizers

(A) Amplifier networks (B) Basic number 16 *P5V* cable equalizer (C) Sum of amplifier network and basic equalizer for 4-megacycle cable loss of 25-decibels

volts (peak to peak) and it is clamped.

When the length of the preceding link is greater than 27 decibels a repeater also is used as a receiving amplifier as shown in Figure 12(B). The signal is clamped and a 2-volt (peak to peak) decibel signal is provided the customer as in the previous receiving terminal. In this case the maximum length of the preceding link is 90 decibels with the extra gain provided by the clamper amplifier. The operation of the receiving amplifier is the same as an intermediate, which will be described in more detail.

The *1B* clamper amplifier provides 18-decibel gain and a 31-decibel reduction of 60-cycle interference and a correction for a loss of low-frequency signal components. It is used in the receiving terminal for gain and to restore the low-frequency signal components after transmission through video repeating coils or over circuits whose length is such that increased low-frequency amplitude or phase distortions may result. The theory of design and the operation of this and other clampers has been presented[4,5] elsewhere and will not be described here.

Intermediate Repeater

The repeater arrangement is shown in Figure 14. In Figure 15 a single repeater with its regulated filament and plate supply panels are shown mounted in a portable cabinet. When a number of repeaters are used in a telephone central office, they are mounted three on an 11 foot relay rack with the necessary cable terminals and interconnecting jack panels as shown in Figure 16. The repeater consists of three principal elements, the input amplifier, the cable equalizers, and the output amplifier as shown in the block diagram of Figure 14.

The input amplifier consists of an input amplifier network, a balanced input stage of gain followed by a cathode output stage connected directly to the line equalizers. A simplified schematic of the input amplifier is shown in Figure 17. The response characteristic of the network is shown on Figure 18 which is part of the cable equalization. The voltage gain of 13 decibels at the high frequencies is part of the total input amplifier gain. Since it raises the high-frequency signal level at the grids the noise figure of the input amplifier is improved 13 decibels. Provision is made to remove the input network when it is not needed as equalization or gain for short cable lengths.

The input longitudinal balance of the amplifier to keep down 60-cycle pickup is provided by the feedback resistance R_K and the balancing adjustment R_1. The longitudinal component at the output resistance R_L of V_3 is

$$e_L = \frac{e_1+e_2}{2} R G_m \left[\frac{K(1+R_K G_m) - R_K G_m}{1+2R_K G_m} \right]$$

where

$$K = \frac{R_2}{R_1+R_2},\ R_2 = 2{,}000 \text{ ohms},\ G_m = 10{,}000 \times 10^{-6}$$

Figure 17. Simplified schematic of repeater input amplifier

The bracket indicates the total of feedback and balance. If the value of $R_1=0$, the bracket gives the feedback reduction which is 32 decibels. If R_1 is adjusted so that

$$K=\frac{R_2G_m}{1+R_2G_m}$$

the bracket reduces to zero and, therefore, eliminates the longitudinal component. It is possible in practice to obtain a reduction of 75 decibels in the low-frequency longitudinal components.

The signal component at the output resistance R of V_2 is

$$e_s=eRG_m{}^1/_2\left[\frac{K(1+R_2G_m)+R_2G_m}{1+2R_2G_m}\right]$$

The loss of the balance circuit is indicated by one half the bracket. If $R_1=0$ the loss reduces to 1/2. If R_1 is adjusted for maximum longitudinal balance as above, the total balance circuit signal loss becomes

$$\frac{R_2G_m}{1+2R_2G_m}$$

which reduces to 20/41 or still approximately 1/2 for the previous circuit conditions. The well-known methods of shunt peaking of the interstage plate resistance R_L is used to obtain a 6-megacycle band which has flat amplitude response and very small phase distortion out to 4 megacycles. The voltage gain of the input amplifier without the input network and terminated in the 1,000-ohm impedance of the cable equalizers is 14 decibels.

The output of the cable equalizers is terminated by the 1,000-ohm input impedance of the output amplifier. This amplifier has three unbalanced gain stages followed by a phase inverter and a balanced output stage. The balanced output stage feeds the balanced cable pair either through the amplifier network or from a 110-ohm termination when it is used as an intermediate repeater. When it is used similarly as a transmitting amplifier its input is terminated in 75 ohms. The voltage gain without the output network, but terminated in 110 ohms is 30 decibels. The normal output operating level is 2 volts (peak to peak) which may be increased 3 decibels for a maximum of three output amplifiers in a circuit. When it is to be used in a receiving amplifier to feed a 75-ohm unbalanced circuit the output is taken from only one of the output tubes terminated in 75 ohms. A simplified schematic is shown in Figure 19. The amplifier network is the same as the one used in the input amplifier having the response characteristic shown in Figure 18. Shunt peaking of the interstage plate resistances is used to obtain a 6-megacycle band which has flat amplitude response and very small phase distortion out to 4 megacycles. Plate load decoupling is used in individual stages to obtain good transient response at the very low frequencies.

Figure 19. Simplified schematic of repeater output amplifier

Over-all Repeater

The tandem operation of many repeaters requires that systematic irregularities be kept to very small limits. Therefore, the response below 4 megacycles is capable of adjustment to ±0.05 decibel in manufacture or subsequent maintenance work if sufficient care is exercised. The greatest part of this irregularity occurs above 2 megacycles and it is practically zero in the more critical region of the band below 500 kc.

The common operating procedure is to receive a 2-volt (peak to peak) signal from the customer, to operate each repeater output at 2 volts (peak to peak) and to return to the customer at the receiving end of the circuit 2 volts (peak to peak) into a 75-ohm load. The low-frequency loss of the cable pair may be anything from near zero for very short circuits to 5 decibels for a 3.5-mile circuit of number 16 *PSV*. Since the input amplifier operates directly from the line its overload at low frequencies is important. The overload in the input amplifier and the output amplifier of a repeater has been kept low so that compression at operating signal levels is negligible with ten repeaters used in tandem.

Equalization of Cable Characteristic

The equalization of the cable characteristic is accomplished by using multiples

Figure 20. Characteristics of variable and fixed cable equalizer units

(A) Slope section (B) Bulge section (C) Sum of both sections each of which are adjustable in the variable equalizer

of three constant resistance equalizer units located between the input and output amplifiers. These equalizers are referred to as basic, fixed, and variable.

The basic is always associated with an amplifier network. Referring to Figure 18 it will be seen that the sum of the characteristics of the amplifier network and the basic equalizer gives curve *C* which is the inverse characteristic of number 16 *PSV* cable loss. It has been plotted as response instead of loss so it may be recognized easily as proportional to the number 16 *PSV* cable characteristic shown on Figure 6. This combination of units will equalize 25 decibels of 4-megacycle number 16 *PSV* cable loss.

The fixed unit will equalize 10 decibels of 4-megacycle number 16 *PSV* loss. The 10-decibel step of the variable unit has the same characteristic as the fixed unit. The variable unit is adjustable in 12 proportional 1-decibel steps. It consists of two sections in tandem. The sum of these two sections gives the desired loss characteristic *C* as shown in Figure 20. Each section is independently adjustable to give the 12 proportional 1-decibel steps referred to previously.

There is a very small amount of residual high-frequency phase deviation in each repeater link that is removed by the phase equalizer indicated in the repeater block diagram.

Space for five cable equalizer units is provided on a panel located between the input amplifier and the output amplifier as seen in Figure 15. A variable unit and the correct number of basic and fixed units are thus connected in tandem to equalize a given length of cable preceding a repeater. Since there can be a maximum of two amplifier networks per repeater, a maximum of two basic equalizers may be utilized per repeater. The first of these two networks to be utilized in equalizing a line is the output network at the preceding repeater. If the 4-megacycle line loss is 50 decibels or greater the repeater input network is added. Fixed and variable equalizers are then added as needed for longer lengths of cable. The gain of the amplifiers with the equalization that is provided allows for a maximum repeater spacing of about 3.5 miles of spirally shielded number 16 *PSV* or 63-decibel line loss at 4 megacycles.

The general result of the equalizer loss is to attenuate low frequencies more than high frequencies and in the proper amount so that over-all response of the line and equalizer is uniform to a transmitted signal. The impulse noise, originating at the receiving end of the cable, with the cable and amplifier input noise become attenuated with the low-frequency signal components. Therefore, there is a noise reduction in the low-frequency region. There is, also, a reduction in the interfering effect of the noise due to its concentration in the high-frequency band. The use of the output network at the preceding repeater as part of line equalization increases the high-frequency sending level 13 decibels without increasing the overloading in the output amplifier. This results in an added noise improvement of 13 decibels.

Noise Reduction by Signal Predistortion

The use of the predistorter at the transmitting terminal results in an added noise reduction for long repeater links. The predistorter characteristic is given in Figure 10. The 20-decibel low-frequency loss is made up at the first repeater. When 20 decibels of gain is used at the first repeater to make up for the 20-decibel low-frequency loss of the predistorter, the high-frequency signal components are thereby increased on the outgoing line. This predistorted signal shape is retained throughout the remainder of the circuit. It is finally restored to its original shape at the receiving terminal, by the use of a complementary equalizer characteristic shown in Figure 10. Since this restorer has the high loss characteristic shown at the high frequencies it, also, attenuates high-frequency noise. This results in an average improvement in signal-to-impulse noise of 16 decibels and an improvement of almost 20 decibels in the signal-to-random noise from the cable and input amplifier. However, this reduction of noise is not obtained without some penalty. The load capacity of the repeater output stage must be increased some 4 decibels because of the adverse peak factor of the pre-equalized signal. The net gain in signal-to-noise ratio is, therefore, 4 decibels less than the values just given.

Circuit Application

The application of this video transmission system can best be shown by the use of two typical number 16 *PSV* circuit cases.

The simplest circuit case is the one where a central office repeater is located between the transmitting and receiving terminals as shown in Figure 21. In this case the circuits are short and noise protection is not needed. The maximum cable slope characteristic that can be equalized in this case is $L_1+L_4=69$ decibels, with the restriction that $L_4 \leq 27$ decibels. This restriction is necessary to prevent the output amplifier from overloading on the high peaked signals resulting from the pre-equalization for the final link. In the case shown in Figure 21 the loss of L_1 and L_4 are 32 decibels and 20 decibels respectively. The transmission response of the circuit is as shown in the figure.

A more complex circuit application is illustrated in Figure 22. The total length of the five video lines is 11.72 miles having a total 4-megacycle loss of 211 decibels. Also, it will be observed that line L_3 is 5 miles in length with a 4-megacycle loss of 90 decibels and the normal operating procedures must be modified to accommodate this special case.

There is not enough gain or equalization in repeater R_3 to operate a 90-decibel line. However, it is accomplished in this case by altering the operating procedure in three ways. First, it is permissible to operate the output of repeater R_1 at a level which is 3.5 decibels higher than normal. Second, since line L_3 is short the output network in repeater R_3 can be used in the equalization of line L_4. This equalization occurs in the form of 13 dec-

CIRCUIT	MILES	4-MC LOSS IN DECIBELS

Figure 22. More complex circuit application of *A2* video transmission system

ibels of high-frequency gain instead of low-frequency loss. Third, since line L_4 is short there is no noise protection problem at repeater R_4 so that the output level of repeater R_4 can be operated the necessary 10 decibels lower than normal. The signal arrives at repeater R_5 10 decibels lower than normal and is raised to normal by use of excess gain in repeater R_5. In this manner the 27 decibels of gain has been obtained to increase the normal repeater spacing of 63 decibels to 90 decibels. This cannot always be done and it is seldom desirable to deviate from a standard operating procedure but in this case it made the operation of an off premise extra repeater unnecessary.

The remainder of the circuit follows normal operating procedure. A final mop-up equalizer is located at the receiving terminal to reduce the amplitude of the residual transmission distortion characteristic. The over-all transmission characteristic is given in Figure 22.

Conclusion

The *A2* video system just described makes use of new repeating coils and new low-loss cables. The new clamping techniques are utilized to restore low-frequency components that may be lost in transmission, reduce low-frequency interference, and improve the low-frequency stability in general of long video circuits.

The video transmission system is ordinarily applied according to a standard operating procedure. However, it has been shown by a complex circuit application that it can be flexibly applied to care for difficult nonstandard operating conditions.

No Discussion

A Negative Impedance Repeater

J. L. MERRILL, JR.
NONMEMBER AIEE

IN SPITE of the increasingly widespread use of carrier, coaxial and radio in the long distance plant of the Bell Telephone System, the basic transmission medium for distances in the order of 20 miles or less, is the 2-wire circuit operating at voice frequencies. Such lines serve to link a subscriber's telephone set to its associated central office and to interconnect the various central offices within an area covering a city or a group of towns, known as an exchange area. To improve transmission on these exchange-area lines a new type of device, the negative impedance repeater, has been developed.

As the nation has grown, the exchange area plant has been continually extended and rearranged to meet the changing conditions of the times. Shifts in population or demands for new or special telephone services have required either that some additional device be developed to improve transmission over existing lines or that new facilities having a lower transmission loss per-unit length be installed. One of the first devices developed to lower the loss per-unit length of a copper wire line was the loading coil; and loading coils have found application in the exchange area as well as in the toll plant. Another device developed to reduce circuit loss was the voice frequency repeater, which made the first transcontinental line feasible. However, because of the amount of equipment necessary for 2-wire application, this type of vacuum tube repeater did not prove generally to be an economical answer to the problem of reducing line attenuation in the exchange area.

The negative impedance repeater described herein, designated the *E1* telephone repeater, has been designed specifically for application in exchange area circuits. While it has few parts, it is complete in that it does contain all the equipment necessary for direct insertion in a 2-wire line. Its "package" nature simplifies the equipment and engineering aspects of installation. There are no external jacks, coils, or networks to be associated with it.

The principal field of use of the *E1* repeater appears to be on tandem trunks, toll connecting trunks, and special service lines. In an exchange area some central offices are connected directly with each other by means of direct trunks while others are connected together through an intermediate switching point known as a tandem office. As compared to direct trunking of all calls, tandem switching results in a smaller number of and more efficient trunk groups. However, tandem trunking involves greater distances than direct trunking and hence can require a lower loss per-unit length of line. *E1* repeaters may provide an economical means of reducing transmission losses on trunks from a distant office to tandem. Similarly, they may be used to lower the loss of a trunk connecting a local central office to a toll switching point. Also they may find important application where a subscriber requests a special telephone service and the use of existing line facilities alone would result in poor transmission.

Features

The *E1* repeater consists of three basic parts, Figure 1, a transformer, an amplifier, and a network. The transformer couples the amplifier to the telephone line through two balanced windings, one inserted in each line conductor. The amplifier is a feedback arrangement referred to as a negative impedance converter because, in effect, it transforms the impedance of the network into a negative impedance. This negative impedance is inserted in series with the line by means of the transformer. The network is adjustable. Its impedance determines the voice frequency gain introduced by the repeater, and no other gain control is provided.

No gain is provided for low-frequency signaling current. Direct current can pass through the line windings of the transformer with but slight impairment to d-c supervision (about 40 ohms). Ringing currents, 20 cycles per second, and dial pulses pass through with moderate loss.

The Western Electric Company *407A* vacuum tube used in the amplifier is a twin triode of the miniature type. The two heaters of the *407A* connected in parallel draw 100 milliamperes from a 24-volt central office supply, or connected in series draw 50 milliamperes from the 48-volt supply (power drain in either case 2.4 watts). The plates operate at 130 volts and each one of the two draws 5.5 milliamperes (power drain for the two plates is 1.5 watts). For special applications with an a-c operated power supply a *2C51* vacuum tube can be operated with 6.3 volts on the heater and 130 volts on the plates.

The network contains a number of inductors, capacitors, and resistors which are brought out to terminals on a block under a can cover. Various impedance combinations are available depending

The writer acknowledges the help of K. S. Johnson, P. B. Llewellyn, R. C. Mathes, G. C. Reier, and K. O. Van Wynen, all of the Bell Telephone Laboratories, in evolving the concept of negative impedance expressed herein. He also acknowledges the contributions of W. J. Kopp and J. A. Weller, also of the Bell Telephone Laboratories, to the theory and practical design outlined herein of the negative impedance converter of the *E1* type.

upon the pattern in which these terminals are interconnected or "strapped." The strapping is determined by the type of line facility with which the repeater is to be associated and by the amount of gain required. Two typical network configurations are shown in Figure 2. Both the gain obtainable and the power handling capability of the *E*1 repeater are ample. The maximum usable gain (integrated over a voice frequency range of about 300 to 3,500 cycles per second) is about 10 decibels. The gain at any one frequency may differ somewhat from this integrated value. Because of the impedance relationships found in the exchange plant greater gain than 10 decibels would seldom be usable from any 2-wire repeater. The gain of the *E*1 is the same for both directions of transmission. The repeater will handle without noticeable distortion speech volumes of +10 volume units, and can be located at any point in a circuit since, with present telephone instruments at least, overloading is not a factor.

Method of Application

For most telephone applications the *E*1 repeater can be considered as a negative impedance connected in series with a line. The action of the amplifier can be thought of as converting the impedance of the network to a negative impedance which is coupled in series with the line by means of the line transformer.

In general, a negative impedance inserted at random in a line will provide a transmission gain by increasing the flow of current. It also will produce reflection effects. These reflection effects can be reduced to tolerable proportions by the expedient of limiting the amount of negative impedance allowed under various circumstances, which means limiting the repeater gain. When inserted in a cable circuit a single *E*1 repeater can reduce the loss of a line to about one half of that of the nonrepeatered line without producing noticeable reflection effects. However, more gain can be obtained from a repeater when connected at about the middle of the line than can be had from the repeater when located at or near one end. Where a line consists of a nonloaded section of cable joined to a coil-loaded section maximum permissible gain will be obtained, in general, when the repeater is located at the junction of these two line facilities.

Figure 1. Block diagram of *E*1 telephone repeater

When any lumped impedance, positive or negative, is inserted in a smooth transmission line reflection effects will result unless these effects are phased out in a way similar to that used with coil loading. In general, the term "loading" implies the methodical addition to a uniform transmission line of some impedance or impedances for the purpose of changing the transmission characteristics of the line. For the most part loading is applied for the purpose of reducing line attenuation. It also will change the velocity of propagation and the characteristic impedance of the line. Loading sections need not be of the same length as long as they have about the same impedance where they are joined together, preferably at midsection. Loading with coils adds inductance and thereby reduces the attenuation of a line, decreases the speed of propagation along it and increases the magnitude of the characteristic impedance seen at midsection. Loading with negative impedance adds negative resistance and inductance. This type of loading can be made to reduce line attenuation, increase the speed of propagation, at least at the lower frequencies, and decrease the value of the mid-section characteristic impedance with reference to the characteristic impedance of the nonloaded line. In general, the speed of propagation on lines loaded with negative impedance will materially exceed that of coil-loaded lines. Because of the greater speed of propagation the distance between loading points can be greater with negative impedance loading than it can be for coil loading for the same band of frequencies transmitted. Furthermore, negative impedance loading can reduce line attenuation below that possible with coil loading because the negative resistance element supplies additional power to a line. At present, negative impedance loading appears to be a side issue to the main application of *E*1 repeaters which consists of connecting a single repeater in a coil-loaded or a nonloaded line. These repeaters will be located in convenient central offices.

As mentioned, an *E*1 repeater can be applied on the basis that it is a 2-terminal negative impedance and as such can be inserted in series with a telephone line or other impedances. Thus the repeater may be considered as containing two fundamental elements rather than the three parts shown in Figure 1. The repeater can be considered as consisting of a positive impedance network and a converter whose function is to multiply the impedance of the network by a factor which transforms this positive impedance into a negative impedance. The amplifier and transformer of Figure 1 are both part of this negative impedance converter.

The Negative Impedance Converter

The idea of negative impedance originated over 30 years ago, and was associated with the concept of resistance neutralization. This concept was based on the fact that a 2-terminal device containing a feedback amplifier, an electric arc, or some semiconductor inserted in series with a single mesh circuit could produce the same current flow as would flow otherwise were a resistance R removed from this mesh. Thus, in effect, the device could neutralize[1] an amount of resistance equal to R. Within certain frequency limits such a device could be treated as a negative resistance equal in magnitude to $-R$. However, negative resistance cannot be completely dissociated from reactance at many of the frequencies in the band which must be studied in order to make certain of stability. Consequently, the term negative impedance is used herein to designate the effect produced by a 2-terminal device which has the property of negative re-

Figure 2. *E*1 repeater network

Figure 4 (right). The E1 converter

Figure 3 (above). The negative impedance converter

sistance at some frequencies, negative resistance plus reactance at other frequencies, and positive impedance at still other frequencies.

Heretofore, a number of feedback amplifier circuits have been devised for producing negative impedance. These circuits can be described as converting positive impedance into negative impedance. In general, they can be reduced to an electrically equivalent, 4-terminal network consisting of a combination of positive impedance elements together with an approximately ideal negative impedance converter.

An ideal negative impedance converter, Figure 3(A), resembles a form of transformer: it has a ratio of transformation of $-k:1$, can have four terminals and is capable of bilateral transmission. Assume that a positive impedance Z_N is connected to terminals 3 and 4 and $-kZ_N$ is seen at terminals 1 and 2, Figure 3(B). Then it must follow from the theory described herein that if a positive impedance Z_L is connected to terminals 1 and 2, a negative impedance $Z_L/-k$ will be seen at terminals 3 and 4, Figure 3(C).

George Crisson stated[2] that there are two types of negative impedance which he defined as the series type and the shunt type respectively. His series type is the reversed voltage type of negative impedance $-kZ_N$ equivalent to $-E/I$; and his shunt type is the reversed current type $Z_L/-k$ equivalent to $E/-I$. This is a logical development considering that impedance Z equals E/I, and therefore negative impedance $(-Z)$ equals either $-E/I$ or $E/-I$ where E is the voltage measured across the impedance and I is current flowing through it.

A practical converter circuit can be represented by Figure 3(D). A vacuum tube circuit contains positive impedance elements. Some of these will show up in the equivalent circuit on the left-hand side of the ideal converter; others will show up on the right-hand side of the ideal converter. This will be clarified in the discussion of the E1 circuit which follows. The equivalent circuit of any practical negative impedance converter of this type can be represented by the equivalent circuit of Figure 3(D) which shows the positive impedance elements associated with the vacuum tube in the form of two equivalent networks (N_1 and N_2) arranged one on each side of the ideal converter (C) having a transformation ratio of $-k:1$.

The circuit of the negative impedance converter used in the E1 telephone repeater is a new converter circuit. It consists of a transformer, two triode tubes, a resistance-capacitance network and an inductor, Figure 4(A). The transformer T couples the cathodes of the two tubes to terminals 1 and 2. The tubes work in push-pull and are biased for class-A operation. The resistance-capacitance network couples the plate of each tube to the grid of the other. The inductor L supplies plate current.

By the application of circuit theory, an equivalent circuit for Figure 4(A) can be found, Figure 4(B). In obtaining this equivalent circuit the two tubes have been assumed to be identical. Thus the converter used with the E1 repeater can be reduced to a 4-terminal network consisting of (reading from left to right): the equivalent circuit of the line transformer T; the two biasing resistances R_3; the two plate resistances R_p divided by $(1+\mu_2)$; the ideal negative impedance

converter C of ratio $-(\mu_1-1)/(\mu_2+1)$ to 1; the elements in the resistance-capacitance coupling arrangement which appear in shunt across terminals 3 and 4; the inductor L also shunted across these terminals; and the capacitor C_X which has been added to represent both the distributed capacitance of the windings of L and the capacitance between vacuum tube plates.

It should be noted that μ_2 is the amplification factor of each tube; and that μ_1 equals $\beta_1\mu_2$ where β_1 is a proportionality factor representing the fraction of the voltage, between the plate of one tube and ground, which is fed back to the grid of the other tube. The value of β_1 depends upon the values of C_1, R_3, R_5, and C_2 of the resistance-capacitance coupling circuit. If β_1 approaches unity in value then μ_1 approximates μ_2. If this is so and if both μ_1 and μ_2 are relatively large in magnitude compared to unity then the ratio of transformation, $-(\mu_1-1)/(\mu_2+1)$ to 1, approaches although it can never equal $-1:1$. Furthermore, at both high and low frequencies μ_1 will have a definite phase angle.

With reference to Figure 4(B), it may be obvious how most of the positive impedance terms come to be in this equivalent circuit, but the factors $-(\mu_1-1)/(\mu_2+1)$ and $2R_p/(1+\mu_2)$ may require more explanation. While no attempt will be made here to derive the equivalent circuit, Figure 4(B), some idea as to how these factors, which are essential features, happen to appear in feedback circuits of this type can be had from a study of Figure 5. This figure represents a simple single tube circuit similar to the $E1$ circuit. The line coil has been removed for simplicity, as well as one of the vacuum tubes. To terminals 1 and 2 has been connected an impedance Z_L; and to terminals 3 and 4, an impedance Z_N. The voltage e is an alternating voltage applied in series with impedance Z_L. The instantaneous polarity of voltage e is as shown, and it is assumed that the current i caused by this voltage will flow in the direction indicated at the time under consideration. Let μ be the voltage gain of the tube, R_p be the plate resistance, and β:1 be the voltage ratio of the ideal transformer inserted between the grid and the plate of the tube. Furthermore, let it be assumed that the tube is operating class A so that no grid current flows and the result is a simple series circuit through the cathode and plate of the tube. The effect the grid will have on this flow of current will be to multiply the voltages appearing between cathode and grid by the amplification factor μ and to add these voltages in series in the simplified circuit. The voltages between cathode and grid are: the driving voltage e itself, the voltage drop across $Z_L(iZ_L)$ and the voltage drop across Z_N as seen across the transformer windings in series with the grid (the voltage $i\beta Z_N$). The voltage iZ_L, being a voltage drop, would be considered as having a sign opposite to that of e. The voltage $(i\beta Z_N)$ is assumed to have the same sign as e and the polarity of the coil windings of the ideal transformer can be arranged to make this so. Thus the action of the tube grid can be replaced by a voltage of $\mu(e-iZ_L+i\beta Z_N)$. Therefore, the simplified circuit of Figure 5(B) can be substituted for Figure 5(A), and a solution can be found as shown for the impedance Z seen looking into terminals 1 and 2.

$$Z=\frac{R_p}{1+\mu}-\frac{(\mu\beta-1)}{(\mu+1)}Z_N \qquad (1)$$

Thus looking into terminals 1 and 2 there is seen an impedance $R_p/(1+\mu)$ in series with an impedance Z_N which is multiplied by $-(\mu\beta-1)/(\mu+1)$, the transformation ratio of an ideal converter. The transformation ratio can be expressed as $-(\mu_1-1)/(\mu_2+1)$ to 1. In one sense this transformation ratio represents the action of both positive and negative feedback. If μ_1 approximates μ_2 in both magnitude and phase, and if this magnitude is large compared to unity then the trans-

formation ratio would be relatively independent of variations in μ.

As an illustration of how the elements in this type of circuit may be proportioned, consider the $E1$ design. Here the ratio $-(\mu_1-1)/(\mu_3+1)$ to 1 is $-0.9:1$ over most of the voice frequency range. This is not the over-all ratio of transformation of the device, but only the ratio of the ideal converter C, Figure 4(B). The impedance ratio of transformer T and the effect of the other circuit elements must be considered in determining the over-all effect of the converter from terminals 1 and 2 to terminals 3 and 4. The transformer ratio is 1:9 from terminals 1 and 2 to the tube cathodes. The shunt arms of the networks on both sides of the ideal converter C are relatively high compared to the impedances between which this converter has been designed to operate at voice frequencies. Therefore, these shunt arms can be disregarded at voice frequencies, although at frequencies above and below the voice band they represent a problem for the circuit designer from the viewpoint of circuit stability. The series arms such as $2R_p/(1+\mu_3)$ and $2R_3$ could be cancelled out by adding in series on the right-hand side of the ideal converter a resistance of 1,800 ohms (not shown in Figure 4). The final result is that the impedance seen looking into terminals 1 and 2 of the $E1$ converter when 1,800 ohms plus a network Z_N is connected to terminals 3 and 4 equals $-0.1\ Z_N$ within a reasonable percentage of error over the frequency range from about 300 to 3,500 cycles per second for values of negative impedance from about 100 to 2,000 ohms. Actually this multiplying factor of -0.1 has a slight phase angle at frequencies other than about 1,000 cycles per second which must be taken into account for detailed design work.

In the $E1$ design two line windings instead of the one shown connected between terminals 1 and 2 in Figure 4(A) are provided on transformer T. In practice one of these windings is inserted in each side of the telephone line in a balanced arrangement. Terminals 1 and 2 are thus effectively connected in series with the line, and the $E1$ repeater inserts in the telephone line a reversed voltage type of negative impedance $(-E/I)$, which is the means of introducing additional power in the line, thereby providing a transmission gain.

Stability

Like any amplifier whose output connects back to its input, the negative impedance converter can run away with itself and oscillate if not properly terminated. Fortunately, the criterion for determining stability is simple. Consider again the ideal converter, Figure 3(B). Assume that Z_L, not shown on Figure 3(B), is an impedance connected to terminals 1 and 2. Consider the circuit mesh formed on the left-hand side of the ideal converter by the connection of Z_L to terminals 1 and 2. Here a negative impedance $(-kZ_N)$ is seen looking into terminals 1 and 2, and a positive impedance (Z_L) is seen looking away from them. The total impedance in this mesh is Z_L-kZ_N. If kZ_N should equal Z_L then the total impedance would be zero; and a voltage inserted in series with this mesh would call for infinite current, a situation obviously impossible. Thus it becomes evident that kZ_N should not equal Z_L; or, what is the same thing, the ratio kZ_N/Z_L should not equal 1/0 if the system is to be stable. From a practical engineering viewpoint, a simple rule for judging stability can be stated as follows: The ideal negative impedance converter will be unconditionally stable provided that the magnitude of kZ_N/Z_L is less than unity at any frequency where the angle of this ratio is zero.

This same rule for stability applies to any practical converter circuit, Figure 3(D). However, Z_L must be taken as the impedance seen looking into the network N_1 from the position of the ideal converter C, and Z_N must be taken as the impedance seen looking into network N_2 from the ideal converter C. In other words, the effect of N_1 must be included in Z_L and the effect of N_2 must be included in Z_N.

Actually, the proper handling of N_1 and N_2 to insure inherent stability of a negative impedance converter is the job of the circuit designer just as the elimination of parasitic oscillations of any kind is his concern. The engineer who applies these devices in the field does not have to bother with such details.

Impedance Characteristics

Figure 6 presents an example of an impedance characteristic of the $E1$ repeater, Figure 4(A), as viewed from terminals 1 and 2 with a resistance connected to terminals 3 and 4. The impedance locus is plotted on the resistance-reactance plane. Frequency is taken as the "running" parameter and the impedance is presented for the frequency range from zero to infinity. At zero frequency this impedance would be a small positive resistance equal to the d-c resistance of the primary windings of transformer T. At some low frequency f_1, Figure 6, the locus would show a positive impedance. In the $E1$ repeater it is this portion of the impedance characteristic which is used for the passage of low frequencies such as ringing, dialing, and so forth. Between the frequencies of f_2 and f_3, Figure 6, is seen an impedance which approximates a negative resistance.

This is the operating frequency range of the repeater. At high frequencies the locus would approach the origin again. In Figure 6 this approach is shown through the first and then the fourth quadrant. At frequencies above the speech band passed by the telephone line a negative impedance is not wanted. From Figure 6 it can be observed that if a resistance R is connected to the network terminals (3 and 4) of a negative impedance converter, then, between frequencies f_2 and f_3 which define the operating frequency range of the device, the impedance seen at terminals 1 and 2 can be represented by kR where k is a conversion factor having an angle approximately equal to 180 degrees. The factor k includes not only the effect of the transformation ratio $-k:1$, but also the effect of the positive impedance networks in the converter provided that the impedances between which this 4-terminal device is operating are within the range of impedances between which it has been designed to operate. In this respect the negative impedance converter is like a transformer. Furthermore, if a network having an impedance Z_N is connected to terminals 3 and 4 then at terminals 1 and 2 will be seen an impedance equal to kZ_N which will be a negative impedance between frequencies f_2 and f_3.

The question of stability becomes a relatively easy problem in the application of a properly designed negative impedance of the reversed voltage type. If the network used with the converter is designed to have an impedance characteristic similar to the sum of the two line impedances (line 1 and line 2 of Figure 1) and if the magnitude of the sum of these two impedances is greater than kZ_N at all frequencies the system will be stable. It should be noted that k is the conversion factor only for the band of frequencies between f_2 and f_3. However, in a properly designed converter the magnitude of the negative real component of k will be greater within this band of frequencies than it will be outside this band. Hence, any error in the assumption that k applies at frequencies outside the band defined by f_2 and f_3, in most cases, will be on the side of increased stability.

Conclusion

A repeater having the properties of a negative impedance converter can be used in a telephone line for the following purposes:

1. To decrease the transmission loss of a line by the application of a single repeater. This is accomplished with negative impedance by cancelling, in effect, part of the line impedance thus causing an increase in current flow. Of course, the magnitude of the negative impedance should be kept below the value where reflection effects become noticeable. It is expected that most applications will be of this kind where a single *E*1 repeater is used on a tandem trunk, a toll connecting trunk or a special service line.

2. To load a line with negative impedance. By this means it is possible to produce a low loss line without reflection effects.

3. To eliminate a lumped impedance irregularity equal to Z by the series addition to it of a negative impedance equal to $-Z$.

Effect of Three-Phase Motor Loads on Voltage Changes Produced by Single-Phase Loads

M. A. FAUCETT
MEMBER AIEE

M. FISHER, JR.
ASSOCIATE AIEE

M. S. HELM
ASSOCIATE AIEE

THE problem of determining the voltage changes produced by single-phase loads has increased during the past several years. One of the principal reasons for this increase is the application of single-phase resistance welding to many new processes. The usual type of single-phase resistance welder requires for its operation large intermittent values of kilovolt-amperes at a low power factor. This type of load will, of course, produce voltage fluctuations on the power system adjacent to the welder. If these variations are severe enough, they may cause objectionable lighting flicker to the other customers served from the same portion of the power system. The usual range of permissible voltage variation is from 0.5 to 1.5 volts on a 120-volt base. The actual value is dependent upon the type of welder load, whether cyclic or noncyclic, and if cyclic upon the frequency of the load application.

Since such variations are objectionable, it is necessary that the power company engineer be able to determine accurately what the variation in voltage will be in order to provide adequate service at the lowest cost. In general these problems have been handled satisfactorily with considerable ingenuity in devising schemes to keep the cost of service reasonable. However, in some cases voltage drops measured after a welder was installed were appreciably lower than had been calculated. It was reasoned by many power company engineers that this was caused by motor loads adjacent to the welder. In the calculations any possible effect of these motor loads in reducing the voltage changes had been neglected.

It is shown in this paper that there is definitely an improvement in the voltage regulation as a result of motor loads adjacent to a single-phase load. Methods of determining this improvement are given together with the results of some typical calculations. These calculations show that the improvements are large enough to warrant consideration in an accurate analysis of the voltage change produced by a single-phase load.

Analytical Development

General Method of Analysis

In this paper the analysis of voltage changes produced by a single-phase load is made by the method of symmetrical components. The method used is similar to that employed for nonsymmetrical fault calculations.

It is assumed that the single-phase load is the only unbalance on an otherwise symmetrical system. It also is assumed that all currents and voltages are sinusoidal.

In Figure 1, I_a, I_b, and I_c represent the currents flowing to the single-phase load. V_a, V_b, and V_c are the neutral-to-line voltage rises of the respective phases after the load is connected.

Sequence Network Relations

In this analysis ABC is taken as the positive phase sequence and the subscripts 1, 2, and 0 refer to the positive, negative, and zero sequences respectively. The general sequence networks are shown in Figure 2. In this figure F_1, F_2, and F_0 indicate the point of unbalance in the respective networks. V_{a_1} is the neutral-to-line voltage rise of phase A at F_1 in the positive-sequence network. I_{a_1} is the current of phase A flowing from the positive-sequence network into the unbalanced load. V_{a_2}, V_{a_0}, I_{a_2}, and I_{a_0} are similarly defined.

Let V_{F_A} be the positive-sequence neutral-to-line voltage rise of phase A at F before the load is connected. Then by the principle of superposition

$$V_{a_1} = V_{F_A} - I_{a_1} Z_1 \tag{1}$$

where Z_1 is the positive-sequence impedance from F_1 to the neutral bus (generated electromotive forces considered zero). Likewise

$$V_{a_2} = -I_{a_2} Z_2 \tag{2}$$

$$V_{a_0} = -I_{a_0} Z_0 \tag{3}$$

where Z_2 and Z_0 are defined in a manner similar to Z_1. Since the system was balanced originally, there would be no negative- or zero-sequence voltages existing before the single-phase load was connected.

General Equivalent Circuit

Referring to Figure 1, the conditions at the point F are:

$$I_a = 0 \qquad I_b = -I_c \qquad V_b - I_b Z_F = V_c \tag{4}$$

The symmetrical components of the single-phase load currents are:

$$I_{a_0} = {}^1/_3(I_a + I_b + I_c) = {}^1/_3(0 + I_b - I_b) = 0$$

$$I_{a_1} = {}^1/_3(I_a + aI_b + a^2 I_c) = {}^1/_3(0 + aI_b - a^2 I_b) = \frac{a - a^2}{3} I_b$$

$$I_{a_2} = {}^1/_3(I_a + a^2 I_b + aI_c) = {}^1/_3(0 + a^2 I_b - aI_b) = -\left[\frac{a - a^2}{3}\right] I_b$$

$$I_{a_2} = -I_{a_1} \tag{5}$$

The voltage rises at the point F in

Paper 50-236, recommended by the AIEE Electric Welding and Transmission and Distribution Committees and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 17, 1950; made available for printing August 25, 1950.

M. A. Faucett, M. Fisher, Jr., and M. S. Helm are all with the University of Illinois, Urbana, Ill. The problem discussed in this paper was studied in co-operation with the Utilities Research Commission, Chicago, Ill.

Figure 1. Single-phase load considered as a line-to-line fault on a symmetrical 3-phase system

terms of their symmetrical components are:

$$\begin{aligned} V_a &= V_{a_1}+V_{a_2}+V_{a_0}=V_{a_1}+V_{a_2} \\ V_b &= V_{b_1}+V_{b_2}+V_{b_0}=a^2V_{a_1}+aV_{a_2} \\ V_c &= V_{c_1}+V_{c_2}+V_{c_0}=aV_{a_1}+a^2V_{a_2} \end{aligned} \tag{6}$$

Since $I_{a_0}=0$, V_{a_0} must also equal zero.

Using the relations expressed in equations 4 and 6 it can be seen that

$$V_b-V_c=(a^2-a)V_{a_1}-(a^2-a)V_{a_2}=I_bZ_F$$

since

$$I_b=I_{b_1}+I_{b_2}+I_{b_0}=a^2I_{a_1}+aI_{a_2}=(a^2-a)I_{a_1}$$

the preceding equation becomes

$$V_b-V_c=(a^2-a)V_{a_1}-(a^2-a)V_{a_2}=(a^2-a)I_{a_1}Z_F$$

or

$$V_{a_1}=V_{a_2}+I_{a_1}Z_F \tag{7}$$

In order to satisfy the conditions given in equations 5 and 7, the sequence networks must be connected as shown in Figure 3.

I_{a_1} can be found in terms of the sequence network impedances and the voltage existing before the single-phase load is connected. Solving equation 1 for V_{F_A} and making use of equations 2, 5, and 7

$$V_{F_A}=V_{a_1}+I_{a_1}Z_1=V_{a_2}+I_{a_1}Z_F+I_{a_1}Z_1=I_{a_1}Z_2+I_{a_1}Z_F+I_{a_1}Z_1$$

or

$$I_{a_1}=\frac{V_{F_A}}{Z_1+Z_2+Z_F} \tag{8}$$

V_{a_1} and V_{a_2} also can be determined in terms of the sequence network impedances and the voltage existing before the fault. From equations 1 and 8

$$V_{a_1}=V_{F_A}-I_{a_1}Z_1=V_{F_A}\left[1-\frac{Z_1}{Z_1+Z_2+Z_F}\right] \tag{9}$$

and from equations 2, 5, and 8

$$V_{a_2}=-I_{a_2}Z_2=V_{F_A}\left[\frac{Z_2}{Z_1+Z_2+Z_F}\right] \tag{10}$$

Equations for Voltage Changes at the Primaries of the Transformer Bank Supplying the Single-Phase Load

The preceding general relations and equivalent circuit can be used to determine equations for finding the voltages at a given point in a specific circuit. In this section, these general relations are used to determine the voltage changes for the particular circuit shown in Figure 4. This circuit is typical of many single-phase welder supply systems. The voltage changes at the primaries of the supply transformers are of interest to the utility engineer since it is the primary voltage changes which affect adjacent customers. The following analysis will also show the general method of analyzing other circuit configurations.

For the system of Figure 4, let:

E_{S_A} = excitation voltage rise of the source, neutral-to-line (phase A)
Z_{S_1} = impedance of supply (source and line) to positive sequence
Z_{S_2} = impedance of supply to negative sequence
Z_{MP_1} = impedance of motor load and associated transformer bank at P to positive sequence (equivalent Y-Y)
Z_{MP_2} = impedance of motor load and associated transformer bank at P to negative sequence (equivalent Y-Y)
Z_{T_1} = impedance of supply transformer to positive sequence (equivalent Y-Y)
Z_{T_2} = impedance of supply transformer to negative sequence (equivalent Y-Y)
Z_{MF_1} = impedance of motor load at F to positive sequence (Y value)
Z_{MF_2} = impedance of motor load at F to negative sequence (Y value)
Z_F = impedance of single-phase load
V_{Pa1}, V_{Pb1}, and V_{Pc1} = the positive-sequence neutral-to-line voltage rises at the point P after the single-phase load is connected
V_{Pa2}, V_{Pb2}, and V_{Pc2} = the negative-sequence neutral-to-line voltage rises at the point P after the single-phase load is connected
V_{Pab}, V_{Pbc}, and V_{Pca} = the line-to-line voltage rises at the point P after the single-phase load is connected
V_{PAB}, V_{PBC}, and V_{PCA} = the line-to-line voltage rises at the point P before the single-phase load is connected
V_{PA}, V_{PB}, and V_{PC} = the neutral-to-line voltage rises at the point P before the single-phase load is connected

Figure 3. Connection of sequence networks for a line-to-line single-phase load

Using the preceding definitions, the equivalent circuit for the system of Figure 4 is given in Figure 5. The motors in this equivalent circuit have been shown only as impedances and therefore strictly speaking represent induction motors. Synchronous motors in such a circuit must be shown in the same manner as the source, that is, as an excitation voltage in series with an impedance. However, this does not affect the analysis of conditions after the single-phase load is connected since the impedances Z_1 and Z_2 which appear in the solution are defined as the impedances viewed from the point F in the respective networks with all generated electromotive forces considered zero. These definitions can be made as a result of the principle of superposition.

The circuit of Figure 5 is applicable after the single-phase load is connected. In accordance with equations 5 and 8

$$I_{a_1}=\frac{V_{F_A}}{Z_1+Z_2+Z_F} \tag{11}$$

and

$$I_{a_2}=-I_{a_1} \tag{12}$$

where

$$Z_1=\frac{\left[\dfrac{Z_{S_1}Z_{MP_1}}{Z_{S_1}+Z_{MP_1}}+Z_{T_1}\right]Z_{MF_1}}{\dfrac{Z_{S_1}Z_{MF_1}}{Z_{S_1}+Z_{MP_1}}+Z_{T_1}+Z_{MF_1}} \tag{13}$$

Figure 4. A typical system for supplying a single-phase welder load

Figure 2 (left). General sequence networks

Figure 5 (left). Equivalent circuit for the system shown in Figure 4, after the single-phase load is connected

Figure 6 (right). Equivalent circuit for the system shown in Figure 4, before the single-phase load is connected

$$Z_2 = \frac{\left[\dfrac{Z_{S_2}Z_{MP_2}}{Z_{S_2}+Z_{MP_2}} + Z_{T_2}\right] Z_{MF_2}}{\dfrac{Z_{S_2}Z_{MP_2}}{Z_{S_2}+Z_{MP_2}} + Z_{T_2} + Z_{MF_2}} \tag{14}$$

The component of current in Z_{S_1}, due to the single-phase load is

$$I_{P_{a1}} = I_{a_1} \frac{Z_{MF_1}}{Z_{T_1} + \dfrac{Z_{S_1}Z_{MP_1}}{Z_{S_1}+Z_{MP_1}} + Z_{MF}} \times \frac{Z_{MP_1}}{Z_{S_1}+Z_{MP_1}}$$

$$= I_{a_1} \frac{Z_{MF_1}Z_{MP_1}}{Z_{S_1}Z_{MP_1} + Z_{T_1}Z_{S_1} + Z_{T_1}Z_{MP_1} + Z_{MF_1}Z_{S_1} + Z_{MF_1}Z_{MP_1}} \tag{15}$$

Likewise

$$I_{P_{a2}} = I_{a_2} \frac{Z_{MF_2}}{Z_{T_2} + \dfrac{Z_{S_2}Z_{MP_2}}{Z_{S_2}+Z_{MP_2}} + Z_{MF_2}} \times \frac{Z_{MP_2}}{Z_{S_2}+Z_{MP_2}}$$

$$= I_{a_2} \frac{Z_{MP_2}Z_{MP_2}}{Z_{S_2}Z_{MP_2} + Z_{T_2}Z_{S_2} + Z_{T_2}Z_{MP_2} + Z_{MP_2}Z_{S_2} + Z_{MP_2}Z_{MP}} \tag{16}$$

Before the single-phase load is connected, the equivalent circuit is the positive-sequence network shown in Figure 6. In this figure I_A is the load current to the motors at F and V_{PA} is the voltage rise (neutral-to-line) at point P before the load is connected. $Z_{MP_1}{}^*$ is the impedance of the motor load at F as determined from the voltage, current, and power of the motor load before the single-phase load is connected. $Z_{MP_1}{}^*$ is similarly defined. In the case of an induction motor, such an impedance is the same as the impedance determined from the usual equivalent circuit. An impedance determined from the impressed voltage, current, and power factor of a synchronous motor gives a completely fictitious impedance since the equivalent circuit is usually an excitation voltage in series with the synchronous impedance. All other quantities in Figure 6 are as previously defined.

From Figure 6 it is seen that

$$V_{PA} = V_{PA} + I_A Z_{T_1} = V_{PA} + \frac{V_{PA}}{Z_{MP_1}{}^*} Z_{T_1} \tag{17}$$

V_{PA} is the positive-sequence voltage rise at P before connecting the single-phase load. V_{Pa1} is the positive-sequence voltage rise at P after connecting the single-phase load. I_{Pa1} is the component current in Z_{S_1} due to the single-phase load. Therefore by the principle of superposition

$$V_{Pa_1} = V_{PA} - I_{Pa1} Z_{S_1} \tag{18}$$

Likewise

$$V_{Pa_2} = 0 - I_{Pa_2} Z_{S_2} = -I_{Pa2} Z_{S_2} \tag{19}$$

since there was no negative-sequence voltage at P previous to connecting the single-phase load.

Substituting V_{PA} from equation 17, I_{Pa1} from equation 15, and I_{a1} from equation 11 into equation 18

$$V_{Pa_1} = V_{PA}\left[1 + \frac{Z_{T_1}}{Z_{MP_1}{}^*} - \frac{1}{Z_1+Z_2+Z_F} M\right] \tag{20}$$

where

$$M = \frac{Z_{MP_1}Z_{MP_1}Z_{S_1}}{Z_{S_1}Z_{MP_1} + Z_{T_1}Z_{S_1} + Z_{T_1}Z_{MP_1} + Z_{MF_1}Z_{S_1} + Z_{MF_1}Z_{MP_1}} \tag{21}$$

Similarly

$$V_{Pa_2} = V_{PA}\left[\frac{1}{Z_1+Z_2+Z_F} N\right] \tag{22}$$

where

$$N = \frac{Z_{MP_2}Z_{MP_2}Z_{S_2}}{Z_{S_2}Z_{MP_2} + Z_{T_2}Z_{S_2} + Z_{T_2}Z_{MP_2} + Z_{MP_2}Z_{S_2} + Z_{MP_2}Z_{MP_2}} \tag{23}$$

It can be shown by the use of equations similar to equation 6 that

$$V_{Pab} = V_{Pb} - V_{Pa} = a^2 V_{Pa_1} + a V_{Pa_2} - V_{Pa_1} - V_{Pa_2}$$
$$= \sqrt{3}\angle 210^\circ \quad V_{Pa_1} + \sqrt{3}\angle 150^\circ V_{Pa_2} \tag{24}$$

Also

$$V_{PAB} = V_{PB} - V_{PA} = (a^2 - 1) V_{PA}$$
$$= \sqrt{3}\angle 210^\circ \; V_{PA} \tag{25}$$

and

$$\frac{V_{Pab}}{V_{PAB}} = \frac{V_{Pa_1} - V_{Pa_2}\angle 120^\circ}{V_{PA}} \tag{26}$$

In a similar manner

$$\frac{V_{Pbc}}{V_{PBC}} = \frac{V_{Pa_1} - V_{Pa_2}}{V_{PA}} \tag{27}$$

$$\frac{V_{Pca}}{V_{PCA}} = \frac{V_{Pa_1} - V_{Pa_2}\angle 240^\circ}{V_{PA}} \tag{28}$$

Putting the values of V_{PA}, V_{Pa_1}, and V_{Pa_2} from equations 17, 20, and 22 respectively into the preceding relations the

Figure 7. Lettering convention used for a Y-delta transformer bank

following equations are obtained

$$\frac{V_{Pab}}{V_{PAB}}=\left|1-\frac{Z_{MF_1}^*}{(Z_1+Z_2+Z_F)(Z_{MF_1}^*+Z_{T_1})}\times(M+N/\underline{120^\circ})\right| \quad (29)$$

$$\frac{V_{Pbc}}{V_{PBC}}=\left|1-\frac{Z_{MF_1}^*}{(Z_1+Z_2+Z_F)(Z_{MF_1}^*+Z_{T_1})}\times(M+N)\right| \quad (30)$$

$$\frac{V_{Pca}}{V_{PCA}}=\left|1-\frac{Z_{MF_1}^*}{(Z_1+Z_2+Z_F)(Z_{MF_1}^*+Z_{T_1})}\times(M+N/\underline{240^\circ})\right| \quad (31)$$

The voltage ratios given by equations 29, 30, and 31 are given in the form of the absolute value of a complex quantity since usually only the magnitude of the voltage changes are of importance. The results are expressed as a ratio of the voltage existing after and before the single-phase load is connected since usually the actual voltages at a given point would not be known. If, for example, a ratio of 0.985 were obtained, it would indicate that the single-phase load would reduce the voltage in question to 0.985 times its former value or a voltage drop of 1.5 per cent.

Y-Delta Transformer Bank

The equations just given for the primary line-to-line voltages apply only to a delta-delta connected transformer bank. For a Y-delta transformer bank it can be shown that equations 29, 30, and 31 still give the primary line-to-line voltage ratios provided the plus sign between the M and N terms is replaced by a minus sign.

If the ratios of the line-to-neutral voltages of the Y-delta bank are desired, equations 29, 30, and 31 can be used as follows: equation 29 for the ratio V_{Pc}/V_{PC} equation 30 for the ratio V_{Pa}/V_{PA}, and equation 31 for the ratio V_{Pb}/V_{PB}. This is based on the lettering convention for the Y-delta bank shown in Figure 7.

Motor Impedances to Be Used in Voltage Ratio Equations

The impedance $Z_{MF_1}^*$ which appears in some of the voltage ratio equations is always determined from the voltage, current, and power factor of the motor load connected at F before the single-phase load is connected. The values to be used for the other motor impedances in the voltage ratio equations will be influenced by the type of single-phase load which is connected to the system. For some types of single-phase loads steady-state machine impedances can be used while in other cases subtransient or transient values must be used. To help in determining the proper motor impedances, single-phase loads will be divided into the two following types:

1. Loads connected for an indefinitely long time or connected with an "on" period long enough for the system to reach a steady-state condition.

2. Loads connected with an "on" period so short that the system does not reach a steady-state condition before the "off" period occurs.

Synchronous Motors

For most practical problems of voltage changes involving synchronous machines it is sufficiently accurate to neglect the armature resistance and to use cylindrical rotor theory for both nonsalient pole and salient-pole machines. In the latter case, the direct-axis reactance X_d of the salient-pole machine is used as the synchronous reactance X_s of the equivalent cylindrical-rotor machine.

For type (1) single-phase loads, the synchronous reactance $X_s=X_d$ is used for the positive-sequence motor impedance and the synchronous machine negative-sequence reactance X_2 is used for the negative-sequence motor impedance. For type (2) single-phase loads, the synchronous machine subtransient reactance X_d'' should be used for the positive-sequence motor impedance with loads having "on" periods of 2 or 3 cycles or less and the transient reactance X_d' should be used for the longer "on" periods. The negative-sequence reactance X_2 is used for the negative-sequence motor impedance for type (2) single-phase loads since this value is by its very nature a transient value.

Synchronous machine impedances are affected some by saturation, in other words, by the load on the machine and the amount of field excitation. However, this refinement does not need to be considered in this investigation since the negative-sequence motor impedance, which has the most effect of the voltage change, is nearly independent on saturation due to the damper windings used with synchronous motors. The negative-sequence motor impedance has more effect on the voltage change than the positive-sequence motor impedance since it is the smaller of the two. This effect becomes apparent when the voltage ratio equations are used. The experimental data discussed in the following section also show that the magnitude of the field excitation has a minor effect on the voltage change.

Since it is usually impossible in practical cases to know the exact character of the motor loads, sufficient accuracy can be obtained by using values from Table I of typical constants for general purpose synchronous motors. The constants are for motors normally connected to utility lines, that is, 25–500 horsepower and 1,800, 1,200, or 900 rpm. The reactances are given in per unit with stator kilovolt-amperes as the base and the time constants are given in seconds.

Table I. Constants for Small Synchronous Motors

	Range	Average
Unsaturated direct-axis reactance X_d	0.6 –1.45	1.15
Transient reactance X_d'	0.2 –0.5	0.37
Subtransient reactance X_d''	0.13–0.35	0.24
Negative-sequence reactance X_2	0.13–0.35	0.24
Short-circuit transient time constant T_d'	0.5 –0.65	0.58
Short-circuit subtransient time constant T_d''	0.01–0.02	0.015

Induction Motors

The positive-sequence impedance of an induction motor is the impedance determined from the usual equivalent circuit. This impedance depends on the slip S, that is, on the load carried by the motor. The negative-sequence impedance can be determined by substituting a slip of (2-S) for the S of the usual equivalent circuit. This will show that the negative-sequence impedance is for all practical purposes equal to the blocked-rotor impedance. For transient studies involving induction motors an impedance equal to the blocked rotor impedance is used for the positive-sequence impedance. This impedance might be compared to the subtransient impedance of a synchronous machine. Since there is no field winding, there is no impedance of an induction motor which is comparable to the transient impedance of a synchronous machine.

For type (1) single-phase loads, the usual positive-sequence and negative-sequence impedances are used for the motor impedances in the voltage ratio equations. For type (2) single-phase loads, the blocked-rotor impedance should be used as the positive-sequence motor impedance with loads having "on" periods of 1 or 2 cycles; for "on" periods longer than this the usual positive-sequence impedance should be used. For all type (2) loads, the blocked-rotor impedance is used as the negative-sequence motor impedance.

The usual positive-sequence imped-

ance of an induction motor varies with load. In general, this will not need to be taken into account and the full-load value can be used. This follows from the fact that the negative-sequence impedance has much more effect on the voltage change than the positive-sequence impedance. The experimental data discussed in the next section confirms the above as it shows that the load on an induction motor has little effect on the voltage change produced by connecting a single-phase load.

In practical cases where it is difficult, if not impossible, to accurately determine the motor loads, the following induction motor constants may be used. These constants are in per-unit, the kilovolt-ampere base being equal to the output kilowatts (horsepower x 0.746). They are average values for 60-cycle, general purpose induction motors rated 10–500 horsepower and 1,800, 1,200 or 900 rpm.

Full-load impedance	$0.8\angle 27°$
Blocked-rotor impedance	$0.135\angle 70°$

Experimental Data

Several specific cases were investigated in the laboratory to verify the equations that are given in this paper. As a matter of convenience the supply transformer bank was considered to be connected delta-delta in each case that was investigated. In the laboratory this permitted the use of series impedances in place of the actual transformer bank. Tests were made in which the single-phase welder load was connected for both long and short "on" periods, that is, for some of the tests the single-phase load was connected long enough for the system to reach steady-state conditions and for other tests the "on" period was so short that the system did not have a chance to reach steady state.

In each of the cases that were investigated one or both of the ratios $V_{bc}/V_{F_{BC}}$ and $V_{F_{bc}}/V_{F_{BC}}$ were determined from measured voltages and by calculation. The equations for the voltage ratio at the point F, although not given in this paper, are similar to those for the point P. Phase BC, the one supplying the single-phase load, was used for the check between the experimental and calculated values of the voltage ratio. This phase has the greatest voltage change when the transformer bank is connected delta-delta and therefore the calculation of the voltage change on this phase is usually the most important.

In each of the cases the measured and the calculated values of voltage ratio agreed very closely with a maximum difference of less than 1 per cent. This experimental data definitely showed that both induction and synchronous motors cause a reduction in the voltage change produced by a single-phase load and that this change is not appreciably influenced by the load on the motor or by the excitation in the case of a synchronous machine.

Range of the Motor Effect

In order to provide an indication of the improvement that might be expected in a practical case, calculations were made for six actual single-phase welder installations which are served by the Commonwealth Edison Company of Chicago. The voltage changes produced by these welder loads were computed both with and without the benefit of adjacent motor loads.

The results, given in Table III, of the calculations for these six cases show that reductions in the voltage changes of the order of 25 per cent may reasonably be expected. The actual improvements ranged from 12.5 to 27.0 per cent. In each case the improvement on the phase having the maximum voltage drop is of most interest, since it is the maximum voltage change which will determine if the load is to produce objectionable voltage variations. For this reason, the fact that the motor load causes an increase in the change in the line-to-line voltage CA for case number 4 is not objectionable since the line-to-line voltage AB has a greater voltage change.

Table III. Calculated Results

Case Number	Per Cent Change No motors Connected	Per Cent Change All motors Connected	Per Cent Improvement Due to the Motors
Change in Line-to-Neutral Voltage of Phase A			
1	0.77	0.62	19.5
2	0.81	0.61	24.6
3	1.17	0.86	26.5
4	1.04	0.91	12.5
5	1.76	1.44	18.2
6	1.05	0.78	25.7
Change in Line-to-Line Voltage AB			
1	0.54	0.50	7.4
2	0.48	0.42	12.5
3	1.09	0.83	23.9
4	1.14	0.98	14.0
5	1.04	1.02	2.0
6	0.73	0.59	19.2
Change in Line-to-Line Voltage CA			
1	0.61	0.46	24.5
2	0.74	0.54	27.0
3	0.66	0.55	16.7
4	0.41	0.44	−7.3
5	1.60	1.21	24.4
6	0.84	0.64	23.8

As can be seen from the results of these calculations the effect of the motors may be appreciable and should be taken into account in determining whether a single-phase load will produce objectionable voltage fluctuations.

The calculated results given in Table III are expressed in terms of the lettering convention of Figure 7. The voltage changes are all given for the point P, the primary of the transformer bank supplying the welder.

Field Tests

Field tests were conducted at two plants having single-phase welder installations, one plant being supplied at 4 kv and the other at 34.5 kv. These tests were performed to determine how measured voltage drops would compare with those calculated by the method given in this paper using field data. The results checked well within the accuracy normally expected in field tests.

Table II. Circuit* and System Data

Case No.	Welder Load, Kva	Line Voltage, Volts	Welder Power Factor, Per Cent	Duration of Weld in Cycles	Transformer Bank Supplying Welder, Kva	Impedance of Transformers in Per Cent	Resistance of Supply System in Ohms	Reactance** of Supply System in Ohms	Motor HP at P	Motor HP at F
1	72	232	67	30	3–75	2.4	0.538	0.484	2,200	0

4	140	226	98	12	3–50	3.4	0.361	0.403	750	160
5	58	221	60	15	3–25	2.4	1.678	1.151	650	45
6	94	218	47	24	3–37½	2.4	0.380	0.571	2,000	120

* The circuit to which these data apply is shown in Figure 8.

** Reactance of transformers supplying motor load at $P = 4$ per cent (on motor base)

Summary

1. The effect of the motor loads adjacent to a single-phase load is to reduce the maximum voltage variations produced by the single-phase load. In many cases this effect may be appreciable and should therefore be included in an accurate analysis of the voltage changes produced by the single-phase load.

2. The voltage change produced by a single-phase load with the effect of the motor loads included can be calculated on the basis of the method and equations given in this paper.

3. The amount of load on the motor and the excitation in the case of a synchronous machine have little effect on the voltage change.

4. In practical cases it is found that the exact character of the motor load adjacent to the single-phase load cannot usually be determined. It is also found that the motor loads are usually induction motors. Because of this and the foregoing statement concerning the effect of the load on the motor, most practical cases involving single-phase loads with "on" periods longer than two cycles may be handled with sufficient accuracy by using the average full-load and blocked-rotor impedances for induction motors as the positive and negative-sequence motor impedances respectively. For those cases involving an appreciable amount of synchronous motor load it is necessary to use the impedances given previously for synchronous machines. For those few cases involving single-phase loads with an "on" period of two cycles or less the impedances suggested for type (2) single-phase loads should be used.

Figure 8. Welder supply system used in the determination of the voltage changes produced in practical cases

5. Balanced 3-phase loads other than motors have not been considered for two reasons. The first is that the usual industrial load is largely motor load. The second reason is that the positive- and negative-sequence impedances of the other balanced 3-phase loads are equal and therefore they do not affect the voltage change caused by the welder nearly as much as the same kilovolt-amperes of 3-phase motor load. In cases where there are appreciable balanced 3-phase loads other than motors connected to the system, they can be taken into account by including their impedances when setting up the positive and negative-sequence networks.

6. All of the equations given in this paper are based upon sinusoidal currents and voltages. However, there are single-phase welders which have phase-shift heat control and do not draw sinusoidal currents except at the 100 per cent heat setting. There are two types of phase-controlled welders that need consideration. The first is the type which does not use series capacitors for power factor correction. For this type it is recommended that the voltage drop be determined for the 100 per cent current setting since the maximum drop occurs under this condition.[6]

For the second type which uses series capacitors to correct the power factor to approximately unity, the maximum drop in the line-to-line voltage for a delta-delta transformer bank or the line-to-neutral voltage for a Y-delta bank does not occur at 100 per cent current but at a current reduced by phase control.[6] Therefore the maximum voltage drop cannot be determined by the method in this paper since the current would be nonsinusoidal. The solution of this problem was not included in the preceding investigation and remains a problem for further study.

ASSOCIATE AIEE

AEOLIAN vibration and vibration fatigue failure occurring therefrom have been a recognized limiting factor in nonferrous conductor life for many years. During this time, much work has been done in the study of its nature and of protective and preventive measures (see references at end of this paper). In addition, the high-amplitude low-frequency types of vibration, more commonly known as "galloping", have received considerable attention.[1,2,3] This type of vibration, however, will not be discussed here.

Little recognition appears to have been given the problem of steel strand vibration failures, perhaps because of the better fatigue properties inherent in this material. In recent years, failures in steel strand used for shield wires have been reported, seemingly in increasing numbers, particularly in installations utilizing the higher strength types of strand. These failures have not been confined to any one region or to the materials of any one manufacturer.

Since the nature of the failures indicated that the materials were being worked beyond their endurance limits, it appeared desirable to evaluate the appropriate mechanical properties, construction practices, and other factors which might be affecting performance.

Little of the experience gained in the past seems to have been applied to shield wires in spite of the fact that, as early as 1928, samples of vibration failure in ground strands were cited.[4] The remedial measures accruing from the experience with conductors resulted in measurably increased conductor life but the lack of application of this experience to ground strands has been, we believe, a definite contributing factor toward the current situation.

Nature of Stresses

As previous investigators have pointed out,[5] the total stress governing the life of a multiple wire cable is composed of four stress components:

1. Stress due to initial static tension.
2. Bending stress due to static sag.
3. Bending stress due to curvature of the loops in vibration.
4. Increased tensile stress due to the necessary increase in length of cable in a vibrating loop.

Obviously, to insure maximum cable life, the sum of the constituent stresses must not exceed the endurance limit of the material. (Endurance limit is defined as the maximum stress that a metal will withstand without failure during a specified large number of cycles of stress.) This value of working stress may be exceeded when vibration occurs either because of high static tension or because of the occurrence of temperature appreciably below that for which the installation was designed. The thought has been expressed that the endurance limit also might be adversely affected by extremely low operating temperatures.

Object and Scope

A study of the wire and strand properties was instituted to determine:

1. The endurance limit and endurance ratio of the various materials used in overhead ground strands.
2. The effect of operating temperature on the endurance limit of each material.
3. The extent to which the change in elastic modulus caused by temperature changes affected the calculated stresses.
4. The extent to which operating stresses were affected by thermal expansion coefficients of ground strand materials.
5. The effect of working tension on the vibration fatigue life of clamped Extra High Strength galvanized strand.
6. Consideration of possible measures for promoting improved operating performance of ground strands.

Paper 50-237, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 25, 1950; made available for printing August 29, 1950.

Figure 4. Detail of coupling spring arrangement

Figure 5. Typical vibration failure of strand in suspension clamp (shoe and bolts removed)

Apparatus and Testing Procedure

A brief description of the various kinds of testing apparatus used will promote better understanding of the results referred to later. For obtaining endurance data on the component wires of the various strands, the rotating-strut type fatigue testing machine (a modification of the Haigh-Robertson testing machine) was used as shown in Figure 1. For sub-zero temperature tests and for the elevated temperature tests, an insulated box enclosed the specimen, as shown in Figure 2. Cold temperatures were obtained by cooling the air inside the box with "dry ice" while the warmer temperatures were obtained by thermostatically controlled electric heaters.

The thermal expansion and elastic modulus data at various temperatures were obtained in a specially constructed "thermo-extensometer." It is, essentially, a tubular frame having a lever mechanism for applying tension to a specimen which passes through an insulated pipe, also containing an agitated coolant or heating fluid, whichever the test requires. The specimen motion due to temperature change or due to load application, is measured on a dial indicator actuated by the differential motion of two gauge points on the specimen, 100 inches apart.

Vibration fatigue testing at resonant frequencies of the strands was done on special equipment described in an earlier paper.[8] Shown in Figure 3, it consists of a heavy frame and a lever system for tensioning a specimen. In the center is an electromagnetic type vibration transducer, coupled to the specimen by means of a spring. Careful choice of the spring characteristics minimizes the effect of the coupled mass at the center vibrating loop as shown in Figure 4. The specimen, about 35 feet long, is suitably held at the ends in strain clamps and is rigidly supported in suspension clamps, each secured to the machine frame 20 feet apart. Vibration amplitude, one of the most critical factors affecting strand vibration life, is observed by means of a cathetometer focused at the center of a vibrating loop. An automatic shutoff control circuit, sensitive to small amplitude variation, stops the apparatus when a specimen failure occurs. A typical "failed" specimen is shown in Figure 5. In all tests, the clamp bolts were tightened to 50 foot pounds torque. To produce one curve or envelope of amplitude versus life cycles requires testing many separate specimens, each at a different level of vibration amplitude. In the course of these tests, some 3,000 feet of strand was consumed.

Figure 6. Reversed bending fatigue of center wire from 5/16-inch galvanized 7-wire strands (77°F) various grades

Figure 7. Reversed bending fatigue of center wire of 5/16-inch 7-wire strands. Based on per cent of ultimate strength

Experimental Results

To eliminate the extraneous effects due to gripping, clamping or abrasion, wires were first tested in reversed bending endurance, thus reflecting the inherent resistance to fatigue of each material. Test specimens were prepared by unstranding lengths of 7-wire strand, removing the core wire which was then hand straightened. These tests were followed by vibration fatigue tests on the complete strands held in conventional line hardware and under tension.

Endurance Limit Versus Grade

Fatigue curves shown in Figure 6 are the results of samples taken at random from mill production of hot-dipped galvanized strand in Siemens-Martin, High Strength, and Extra High Strength grades. As expected, the endurance limit level of the wire increases as the tensile strength is increased. This relationship, however, is not linear, since the effect of galvanizing tends to limit the endurance limit stress at the higher wire strength levels. This effect is more clearly indicated in Figure 7 showing the wire life as a function of the stress in percentage of ultimate strength. It will be noted that the Extra High Strength wire has the lowest endurance ratio (endurance limit divided by ultimate strength) although it possesses the highest endurance limit.

The graph in Figure 8 shows a comparison of the reversed bending fatigue characteristics at room temperature of hot-dipped galvanized Extra High Strength carbon steel and type *302* stainless steel wire samples. Inherently, the smooth hard drawn surface and the homogeneous nature of stainless steel provide it with improved resistance to fatigue (63,000 pounds per square inch) as compared to the galvanized carbon steel whose (52,300 pounds per square inch) reversed bending endurance limit is influenced by the layer of metallic zinc.

Endurance Limit versus Temperature

Shown in Figure 9 is the effect of stressing Extra High Strength galvanized wire in reversed bending at temperatures from −55 to +200 degrees Fahrenheit. When proper corrections are made for elastic modulus at each temperature, less than 3 per cent change of endurance limit due to temperature was found as indicated by the points within the envelope. The endurance limits were 53,500, 52,300, and 52,000 pounds per square inch for −55, +77, and +200 degrees Fahrenheit, respectively.

Figure 9. Reversed bending fatigue of center wire from $^5/_{16}$-inch Extra High Strength galvanized 7-wire strand at −55°F, +77°F, and +200°F

Figure 10. Reversed bending fatigue of center wire from $^5/_{16}$-inch 7-wire, type 302 stainless steel strand at −55°F, +77°F, and +200°F

Figure 11 (left). Effect of temperature on elastic modulus of $^5/_{16}$-inch 7-wire strand components

Figure 12 (right). Effect of temperature change on tension of $^5/_{16}$-inch, 7-wire strand initially tensioned to 25 per cent of rated breaking strength. (500-foot span)

Figure 10 represents type *302* stainless steel tested in a similar manner. It indicates that a small increase in endurance limit exists at the coldest temperature level, but that no change is in evidence at temperatures above normal. At −55, +77, and +200 degrees Fahrenheit, the endurance limits were 65,000, 63,000, and 63,000 pounds per square inch respectively.

Modulus versus Temperature

The appropriate corrections in computed stress for the elastic modulus at the various temperatures were made by referring to the curves in Figure 11, showing the results of thermo-extensometer tests on the various metals in the temperature range −55 to +200 degrees Fahrenheit.

Tension versus Temperature

Temperature changes, of course, result in variation in strand tension. Figure 12 demonstrates the magnitude of these changes for Extra High Strength steel strand and for type *302* stainless steel strand, both strung to normal (60 degrees Fahrenheit) tensions of 25% of their rated breaking strengths. Here stainless steel is at a slight disadvantage because of its higher coefficient of expansion. It will be noted that at the extreme of −65 degrees Fahrenheit, the tension in a 500-foot span of stainless strand has risen to approximately 36 per cent of rated strength, compared to 34 per cent for Extra High Strength grade. This is, however, partially offset by the previously discussed increase in endurance limit which stainless steel exhibits at low temperatures.

Vibration Fatigue Life versus Tension

The results of the vibration fatigue life tests of 5/16-inch Extra High Strength galvanized strand under various static tensions are shown in Figure 13. The plotted points shown are those which were determined by the number of cycles required to fail the first wire. In all cases, the failures occurred in the strand at a point within the clamp on the top side where the clamp shoe first made full contact. A great amount of scatter in results was experienced and this has been attributed to the susceptibility of extra high strength grade strand to an erratic characteristic performance under high clamping forces. This was the case in all tests regardless of the tension employed. For the purpose of clarity in interpretation, Figure 13 shows for each tension, only the points on the low side of the scatter band. The trend, as would be expected, is one of a decreasing strand life with an increasing tension, when referred to a common amplitude level. It is significant to note that the 2,800-pound tension, amounting to 25 per cent of the ultimate strand strength, is approximately 1 per cent higher than the endurance limit stress of the core wire tested in reversed bending. Obviously, any decrease in tension from this value could be expected to greatly promote strand fatigue life, since it is then more probable that the working stress will not exceed the endurance limit. Increasing tension, on the other hand, only serves to elevate the stress further into the danger zone.

Effect of Armoring

It was found by vibration fatigue testing of 5/16-inch Extra High Strength galvanized strand that the application of galvanized steel preformed armor rods was effective in extending the strand

Table I. Properties of Core Wire Components from $^5/_{16}$-Inch 7-Wire Strands

Material	Tensile Strength, Psi	Endurance Limit, Psi (77°F)	Endurance Ratio, Per Cent
Common galvanized	75,000	35,000	46.3
Siemens-Martin, galvanized	127,000	35,000	27.6
High Strength, galvanized	180,000	50,000	27.8
Extra High Strength, galvanized	220,000	53,300	23.8
Type 302 stainless	236,000	63,000	26.8

Figure 13. Vibration fatigue life of 5/16-inch 7-wire Extra High Strength galvanized strand at various tensions, frequency 65, 85, 98 cycles per second for 1,600, 2,800, and 3,850 pounds respectively. Suspension clamps tightened to 50 foot pounds

Figure 14. Vibration fatigue life of 5/16-inch 7-wire Extra High Strength galvanized strand, tension 25 per cent of rated breaking strength, with and without armor, frequency 78–85 cycles per second, suspension clamps—trunnion type

vibration life many times. This is shown in Figure 14 where tests made on both the unarmored and on armored strand secured in suspension clamps tightened to 50 foot pounds indicated that by the application of armor there was less strand abrasion and chafing, that clamping forces were more evenly distributed, and that a considerable amount of vibration damping was in evidence. Referred to any amplitude level, the life of the armored strand was greater by approximately ten times than that of unarmored strand. Figure 15 shows an armor assembly clamped for testing.

Experimental data appear to confirm the reported field experience that usual tension limitations as specified by the current National Electrical Safety Code[7] may be excessive for the materials commonly used for ground strand. Several possibilities present themselves for the relief of this situation, and may be employed either singly or in combination.

Reduction of the working tension to a value commensurate with the endurance limit of the material would appear to be one logical step. For example, the endurance ratio of Extra High Strength wire is approximately 23.8 per cent of ultimate strength (see Table I). The National Electrical Safety Code specifies a normal (60 degrees Fahrenheit final unloaded) tension of 25 per cent of rated strength. It is felt that a more appropriate limitation for this material would be 20 per cent of rated strength at 0 degrees Fahrenheit. There would then be less likelihood of exceeding the endurance limit of the material under low temperature operation.

Figure 15. Section of test span at clamp having armor applied

In like manner, Siemens-Martin and High Strength galvanized steel strand and type *302* stainless steel strand, all of which exhibit endurance limits near 28 per cent might well be limited to 25 per cent at 0 degrees Fahrenheit, rather than at 60 degrees Fahrenheit. Table II shows the effect that these reduced limitations would have on sags and tensions in a typical span.

Additional insurance against failure may be obtained by the practice of using armor rods at all points of support in locations where vibration is known to be a potential hazard.

A further possibility exists in the use of stainless steel strand, which has a tensile strength equal to that of extra high strength grade galvanized strand, and exhibits a much higher endurance limit, thus safely permitting operation at a higher tensile level.

Much work remains to be done. The relative susceptibility of various materials to clamping stresses may be of importance. Some types of existing hardware leave much to be desired. It is the hope of the authors that the work reported herein will serve to stimulate further investigation and improvement of practice.

Discussion

H. D. Fischer, Jr. (Southern California Edison Company, Los Angeles, Calif.): In connection with the aeolian vibration study being conducted by the Southern California Edison Company, fatigue tests were run on several samples of stranded cable in an effort to determine the effect of the properties on the life of the cable.

The first tests were set up to simulate as nearly as possible the loop lengths and amplitudes which were measured in the field.

Under these conditions failures were not obtained within 10,000,000 cycles and an examination of the cable indicated it would endure indefinitely. The conditions were then exaggerated (the tension being held at 7,000 pounds which is normal line tension) until failure occurred within 1,000,000 cycles for all types of cable being tested. These conditions, 1/8-inch displacement and half loop length of $3^3/_4$ inches with the end connection and center connection being rigidly supported so that bending stresses occurred at both ends, produced the results shown in Table I of this discussion. The physical characteristics of each specimen as determined in the tests also are shown.

The results obtained here indicate a different trend in the endurance limit than those presented in the paper. However, these tests were made on complete 7-strand cable and the connections were of the compression type.

These tests were made in an effort to find some reason for the better performance experienced on one line than that experienced on another, both of which traverse similar terrain and are subject to similar weather conditions. Another point that may be brought out along these lines is that from a vibration standpoint, the performance of lines which are supported by towers with latticed-pyramid type steel footings seems to be better than that of lines supported on towers with rigid cast in place concrete footings.

O. D. Evans (Oklahoma Gas and Electric Company, Oklahoma City, Okla.): The authors of this paper are to be commended for providing the industry with the results of tests made to show the endurance limit and endurance ratio of steel strand used to shield electric power transmission lines from lightning strokes. This information has long been needed and will, no doubt, result in a revision of the steel manufacturing companies' published sag charts and tables to show a reduction in working tensions.

With the advent of long-span steel-reinforced aluminum-cable construction and a better understanding of the function of the shield wires, it became necessary to provide additional clearances between the shield wires and conductors at midspan over that provided at the structure. This increased clearance is required to prevent lightning strokes from spilling over to a conductor at midspan, instead of traveling to the nearest structure and thence to ground.

Additional midspan clearance can most economically be provided in long span lines by using Extra High Strength steel strand cables, if published sag tables put out by the steel manufacturers are used, since these tables show considerably less sag than that of the steel-reinforced aluminum-cable conductors. One steel manufacturer, in the booklet in which such sag tables are published, makes the following statements:

"1. Steel has greater strength and, therefore, can be pulled to less sag than any of the nonferrous conductor materials, thus creating more midspan clearance. Also, steel has better fatigue strength than the other conductor materials, thereby causing less trouble from vibration fatigue failures.

"2. Armor rods are not ordinarily required for use on steel."

The published sag tables of two major steel companies were, therefore, used for stringing steel shield cables on our newer transmission lines so as to realize the benefit of the additional clearance provided at midspan. These sags were calculated by the manufacturers such that under the assumed loading of rule *251* of the current National Electrical Safety Code,[1] the tension would not exceed any one of the following limitations:

1. Fifty per cent of the rated ultimate strength of the cable for the loading specified in the loading district concerned.

2. Thirty-five per cent of the ultimate strength of the cable at 60 degrees Fahrenheit stringing sag without external load.

3. Twenty-five per cent of the ultimate strength of the cable at 60 degrees Fahrenheit final sag without external load.

Numerous breaks have been experienced on the 5/16-inch (7 strand) Extra High Strength steel cables used as shield wires on our newer transmission lines when sagged in accordance with these tables. These breaks can now be readily accounted for in view of the authors' findings that the endurance ratio of 5/16-inch Extra High Strength cable is 23.8 per cent, since the stringing tension at 60 degrees Fahrenheit of the cable in our lines was 28.2 per cent, and the final tension at 60 degrees Fahrenheit was 25 per cent.

It is particularly worthy of note from the authors' paper that, even though the Extra High Strength cable has a higher endurance limit than the High Strength cable, the Extra High Strength cable has a lower endurance ratio than does the High Strength cable. This means that the High Strength cable can be operated at a higher percentage of its ultimate tension than can the Extra High Strength cable without experiencing strand breaks. For example, the endurance ratio tension of 5/16-inch Extra High Strength cable (11,200 pounds ultimate strength) would be 2,665 pounds, whereas the endurance ratio tension of 3/8-inch High Strength cable which has slightly less ultimate strength (10,800 pounds) would be 3,002 pounds, some 337 pounds more than the Extra High Strength cable.

Table II of the paper illustrates the effect of reducing the tension in 5/16-inch Extra High Strength cable and 3/8-inch High Strength cable to obtain tension values at all probable temperatures below their respective endurance ratio tensions. It will be noted from this table that even though the ultimate strength of these two cables is approximately the same, the allowable tensions in the High Strength cable are, at all temperatures, in excess of those in the Extra High Strength cable. Nevertheless, the 5/16-inch Extra High Strength cable has less final sag at 60 degrees Fahrenheit (although the initial sags at 60 degrees Fahrenheit are about the same) and since the 5/16-inch Extra High Strength cable is slightly lower in cost than the 3/8-inch High Strength cable, the 5/16-inch Extra High Strength

Table I

Type of Cable	Per Cent of Rated Ult. Tension	Average Cycles to Failure	Av. Yield Strength, Pounds per Sq. Inch	Av. Ult. Strength, Pounds per Sq. Inch	Average Elongation, Per Cent per 2 In.
1/2-inch 7-strand HS	37.2	563,000	117,000	147,000	14.5
1/2-inch 7-strand EHS	26.0	289,000	167,000	213,000	9.0
1/2-inch 19-strand HS	36.6	892,000	119,000	139,000	14.2
1/2-inch 19-strand EHS	26.2	436,000	150,000	198,000	10.0

HS—high strength. EHS—extra high strength.

cable must still be considered as being more economical for shielding purposes than the 3/8-inch High Strength cable.

According to my understanding of Figures 13 and 14, the "2,800-pound tension" curve of Figure 13 is the same curve as the "without armor" curve of Figure 14, yet, at 0.50-inch vibration amplitude, Figure 13 indicates 3,000,000 cycles whereas Figure 14 indicates 8,000,000 cycles, with both values taken from the lower limits of the scatter band. Since the frequency and clamp pressure is the same in both curves, I am wondering if I have misinterpreted these curves, and if not, what is the authors' explanation of the wide variation in results.

The authors state in their conclusions that the usual tension limitations as specified by the current National Electrical Safety Code may be excessive for the materials commonly used for ground strand. The code requirements state that the tensions shall not exceed the amounts specified, and, in my opinion, do not attempt to set the tensions used. The Aluminum Company of America uses 0 degree Fahrenheit for determining their limiting tensions of $33^1/_3$ per cent initial tension and 25 per cent final tension, instead of 60 degrees Fahrenheit as specified by National Electrical Safety Code rule *261F4*.

The discussion of the National Electrical Safety Code states that operating experience, together with a study of the observed mechanical characteristics of conductor materials under operating and test conditions, should determine the sags. The authors' tests results strongly indicate that the steel manufacturers published sag tables for 5/16-inch (7 strand) Extra High Strength cable will cause strand failures due to aeolian vibrations. The authors' paper also indicates that the published sags for other Extra High Strength and High Strength steel cables are such as to cause strand breakage.

It is, therefore, believed that the steel manufacturing companies should withdraw their published sag data for these steel cables to prevent other companies from encountering strand breaks experienced by the Oklahoma Gas and Electric Company and other companies. Vibration difficulties will be experienced sooner in windy places like Oklahoma but, in my opinion, will be experienced eventually in less windy places if these sag data are used. Sags, in accordance with the authors' conclusions (using 20 per cent of the ultimate cable strength at 0 degree Fahrenheit final tension for Extra High Strength cables and 25 per cent for High Strength cables) seem to be the answer to preventing fatigue failures.

The use of armor rods as additional insurance, as recommended by the authors, also is worthy of consideration, inasmuch as these rods are inexpensive and easy to install, and they provide mechanical protection against clamping stress as well as reducing the effects of vibration.

It is doubtful if the additional cost of stainless steel cables could ever be justified except in those regions where corrosion is a factor.

Reference

1. See reference 7 of the paper.

J. C. Little, D. G. MacMillan, and **J. V. Majercak:** The authors wish to thank both Mr. Fischer and Mr. Evans for their discussion on results of related tests and on power utility viewpoints.

Mr. Fischer shows that High Strength grade strand either of 7-wire or 19-wire construction, had approximately two times greater vibration life than Extra High Strength grade strand when each was initially tensioned to the same load. This apparently occurred in spite of a lesser percentage of rated ultimate strength being used for the Extra High Strength grade strand. It should be noted, however, that all of the initial tensioned stresses employed in the discussor's tests are in excess of the endurance ratio values shown in our paper for each particular grade of strand. It is, therefore, not too surprising to see isolated data indicating a reversal of finite life trend because, in our vibration testing experience, a life variation as great as eight to ten times can exist despite maintaining amplitude variation to less than 5 per cent. Such admittedly erratic performance has been attributed to high and variable stress concentrations produced in the wires of strands held in fitting types exerting high compression forces. The data on which Mr. Fischer bases his discussion supports our belief that were a larger quantity of testing done, the result would be a scatter band with the High Strength test points falling somewhat below the Extra High Strength test points.

The discussor's data showing longer life for the 19-wire strands than the 7-wire strands is in alignment with the lower expected bending stresses developed in strands having smaller wire sizes.

Mr. Evans questions a difference between the location of the 2,800-pound tension curve in Figure 13 and the "without armor" curve in Figure 14. The authors attribute the displacement between the two curves to the use of two different clamp types since no other known variable existed. The difference was not pointed out in our paper since it was not our original intent to condemn or promote any one clamp. In Figure 13 a conventional suspension clamp was used and indicated as "susp. clamp", whereas in Figure 14, the caption bears "trunnion type." Both type clamps were, however clamped rigidly; thus the tests do not reflect either clamp's ability to follow line vibration. The differences in life indicated are probably due to a variation in keeper curvatures and in the different distribution of clamping pressures of the two clamp types.

Since making the original tests, further incompleted testing on stainless steel strand indicates that while the reversed bending endurance limit of its wires ranks highest of the kinds tested, the strand is somewhat more susceptible to the vibration-type stresses than is Extra High Strength grade galvanized strand. It would, therefore, appear that the original suggested limitation on this material (25 per cent of rated strength at 0 degree Fahrenheit for final tension of bare conductor) is excessive, and that it should not be worked at a greater tension than that specified for Extra High Strength galvanized strand.

An Improved Reclosing Relay

L. E. GOFF
ASSOCIATE AIEE

Synopsis: This paper describes a new reclosing relay which offers several features not included in available automatic, reclosing relays. Among the features included are: reset of the relay a short interval after any successful reclosure, to eliminate needless delay in subsequent reclosures and reduce unnecessary lockouts; a simple internal means of blocking the instantaneous trip circuit after the initial circuit breaker trip-out, to facilitate system sectionalizing; immediate first reclosure through an initially closed contact in the relay to reduce first-reclosure time. Operation of the relay and circuit is completely described with emphasis on the operating conditions creating a demand for and the advantages offered by the several improvements. Possible settings and adjustments are discussed which provide a wide degree of versatility in application.

Historical Background

THE desire on the part of operating companies to improve customer service has resulted in the now nearly universal use of automatic reclosing on transmission lines and distribution feeders. The general application of automatic reclosing relays can be traced back for more than 30 years and the history of their development during this period is interesting.

Early schemes for reclosing service assumed many forms and usually involved some combination of timing and auxiliary relays. One form for example made use of a simple plunger-type time delay relay to initiate reclosures and a notching relay to determine the number of reclosures. Since the successive reclosing of a circuit breaker involves essentially a timing operation these early schemes were soon discarded in favor of various forms of motor driven timers with their operation initiated by the opening of the associated circuit breaker. The initial attempt to reclose the circuit breaker occurred after a considerable delay and was followed at intervals by one or more additional attempts to reclose. If the circuit breaker remained closed after the final reclosure attempt the reclosing relay operated to its reset position and was again ready to respond to a circuit breaker outage. If, however, the circuit breaker remained open after the final attempt the reclosing relay stopped in a locked-out position or operated a lockout relay, sounded an alarm, and remained in this condition until steps were taken to reclose the circuit breaker manually.

Operating experience soon indicated that a large portion of the outages on overhead lines were of a transient nature and hence were cleared immediately when the circuit breaker opened. This knowledge led some operating companies to attempt reclosure of the circuit breaker as soon as possible following the initial occurrence of a fault, a step which proved extremely successful and resulted in the modification of then existing reclosing relays by the manufacturers to provide an immediate initial reclosure. From these early designs the present forms of motor-driven reclosing relays, commonly referred to as "multishot" reclosing relays, have evolved with provision for either immediate or delayed initial reclosure, followed by two or more delayed reclosures.

Records made during these early investigations[1] indicated reclosing relay performance as shown in Table I for delayed initial reclosure and for immediate initial reclosure. These figures caused many operating companies to question the need in attended stations for reclosing relays having provision for more than one automatic reclosure, when manual reclosure could produce roughly the same results as the second and third automatic reclosures, and led to the development of the "single-shot" reclosing relays now on the market. Such reclosing relays have more recently seen extensive application on the higher voltage transmission lines where, because of multiple feed, delayed reclosing is not always possible without dead-line or automatic synchronizing and synchronism-check relays. The same figures, however, also indicated a real need for several automatic reclosures in unattended stations. The figures in Table I indicate that there would have been three times as many permanent service interruptions if the immediate initial reclosure had not been followed by a second and third delayed reclosure. Although more up-to-date information[2] now is available on the application and performance of automatic reclosing equipment, when all types of loads are considered it is found that the information in Table I is still remarkably accurate. More extensive experience has indicated, however, that on circuits consisting mainly of residential load the immediate initial reclosure may be successful as much as 90 per cent of the time.

Need for Improved Relay

Since the early addition of the immediate initial reclosure feature there have been no basic changes in the motor-driven reclosing relays offered by manufacturers. In evaluating the improvements which are needed it would be well to first consider some of the requirements which should be met by a modern reclosing relay:

1. Either immediate or delayed initial reclosure should be available, the change from one to the other to be as simple as possible.

2. If immediate the reclosure should be initiated as soon as possible, preferably through a normally closed or "preclosed" contact in the reclosing relay.

3. The reclosing relay should be able to reset automatically a definite time after any successful reclosure.

Paper 50-238, recommended by the AIEE Relays Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 25, 1950; made available for printing August 25, 1950.

L. E. Goff is with the General Electric Company, Philadelphia, Pa.

Table I. Reclosing Relay Performance With Delayed and With Immediate Initial Reclosure

Reclosure	Successful Reclosures Delayed Initial Reclosure, Per Cent	Successful Reclosures Immediate Initial Reclosure, Per Cent
First	85	75
Second	5	15
Third	1	2
Lockout	9	8

4. At least three delayed reclosures should be available, adjustable up to a maximum of three minutes.

5. The reclosing relay must provide pump-free circuit breaker operation.

6. If all reclosure attempts are unsuccessful, the reclosing relay should lock out and remain locked out until the circuit breaker has been successfully reclosed manually.

7. A means should be included in the reclosing relay for blocking the instantaneous trip circuit after the initial circuit breaker outage and prior to the initial reclosure.

While available motor-driven reclosing relays with provision for several reclosures meet most of these requirements, none conform with all of them. Items 2, 3, and 7 are conspicuously absent although they can be of great importance in meeting today's high standards of service reliability.

The use of a preclosed contact in the circuit for immediate initial reclosure places the responsibility of initiating this reclosure on the circuit breaker auxiliary contact which closes when the circuit breaker trips. This results in a reduction in the initial reclosing time by the interval required to operate an auxiliary relay unit, on the order of two or three cycles. While this seems insignificant in itself, it assumes greater importance when total circuit breaker reclosing times in the range of 10 to 20 cycles are considered.

A definite-time reset feature following a successful reclosure also is of great importance. A glance at the column in Table I headed "Immediate Initial Reclosure" shows that operating experience indicates successful circuit breaker reclosure at least 75 per cent of the time on the immediate first reclosure. With available types of motor-driven reclosing relays the relay must time through the entire cycle, or as much as three minutes, before the reset position is reached even though the initial reclosure is successful. If a second transient fault entirely independent of the first occurs within this interval, reclosure of the circuit breaker will be needlessly delayed until the next delayed-reclosure position is reached; or if the second fault should occur during the interval between the final-reclosure position and lockout an unnecessary lockout will result with accompanying lengthy interruption in service. Since the attendant has no way of knowing that the lockout resulted from two entirely independent faults of a transient nature he may, depending upon operating practice of the system concerned, waste additional time in trying to locate a permanent fault which never existed.

It is interesting to note that definite-time reset following a successful circuit breaker reclosure was a feature of the time delay and notching relay combination mentioned in the introductory paragraphs, but was omitted from the more modern motor-driven reclosing relays. Many operating companies have recently indicated that such a feature is now needed, and at least one has developed a reclosing relay using standard relay components[3] which provides quick resetting of the reclosing relay following a successful circuit breaker reclosure.

The use of sectionalizing fuses on branch feeders, described later in detail, depends upon the blocking of instantaneous tripping on first and subsequent reclosures. This has been accomplished previously by an auxiliary unit, either included in the relay or external to it, but can be handled more advantageously by a single contact in the reclosing relay.

A New Reclosing Relay

This paper describes a new circuit breaker reclosing relay and circuit which combines these needed features with those long associated with automatic reclosing relays, and offers a degree of versatility previously unobtainable. The new relay is shown in Figure 1 in its case with cover in place. It should be noted that the case size will represent a reduction of approximately 50 per cent when compared with previously available "multishot", motor-driven reclosing relays. The relay consists essentially of a synchronous driving motor, a gear train and cam shaft with reset spring driven through a crown-gear clutch, a magnetic clutch release, and a series of cam-operated switches for initiating the reclosures and reset attempts and performing the various auxiliary functions essential to the operation of the relay and circuit. A 2-position interlocking relay unit, necessary to obtain the advantage of the preclosed contact on immediate reclosure, and an auxiliary unit which can be used as an antipump relay, also are included in the reclosing relay. All cam-operated contacts are of an enclosed construction

Figure 1. The type *ACR* reclosing relay

with high contact pressure and are of a type used extensively on aircraft where reliability is vital, even at low operating voltages. All components including the motor are insulated to withstand normal switchgear high-potential tests.

The mechanical features of the relay when in the reset position are clearly illustrated by the schematic mechanical diagram in Figure 2. Nomenclature used in the figure and the following description agrees also with designations in the circuit diagram described later. The driving torque is transmitted from the small synchronous motor through a crown-gear clutch consisting of a driving member pinned to the motor shaft, and an idler member. The idler member, which includes a star cam and pinion, is free to slide back and forth on the motor shaft and is normally held in engagement with the stationary member by a compression spring which is a part of the clutch release seal-in switch. The pinion on the idler member drives gear "*A*" pinned to the auxiliary cam shaft causing windup of the reset spring. The auxiliary shaft, which turns through slightly less than 360 degrees during a complete reclosing cycle, carries depressions in its body which operate the roller-actuated snap-action switches "*GH*", "*DE*", and "*JK-KL*" performing auxiliary functions which will be described later. An adjustable cam segment can be set to operate switch "*RS*" at any point in the reclosing cycle. The front dial hub is in turn driven through the gear pair "*B*" and "*C*" and makes slightly less than a half revolution during the complete reclosing cycle.

The dial hub carries a set of double-ended adjustable cams "*D*" which operate switch "*AB-BC*" to initiate delayed reclosures, and switch "*MN*" to reset the relay in the event of a successful reclosure.

These cams consist of round flat plates with diametrically opposite projections which operate the roller actuators. The interval between a delayed reclosure, initiated by the operation of "*AB-BC*", and a subsequent reset attempt, initiated by the operation of "*MN*", is determined by the location of switch "*MN*" in relation to the reclosing switch "*AB-BC*" and thus is the same for all delayed reclosures. The interval between immediate initial reclosure and resetting of the relay if the reclosure is successful is determined by the setting of cam "*E*". This cam actually consists of three separate plates each with a single projection. For the normal adjustment of the relay indicated in Figure 2 these plates are arranged so that the projections are back-to-back, providing in effect a single cam projection. The contribution of these single-ended cams to the versatility of the relay is described in a later section.

Resetting of the relay is accomplished by energizing the clutch release magnet which attracts the release armature and draws the idler member of the clutch away from the fixed member. This permits the gear train, cam shaft, and dial hub to return to their reset position under the influence of the charged reset spring. During the reset cycle the escapement follower retards the motion of the star cam reducing the reset speed to a point where there will be no rebound when the reset position is reached. The clutch release unit is equipped with a seal-in contact to shunt the reset contact "*MN*" during the reset cycle. A manual release rod is provided to permit releasing the clutch from the front of the relay so that the gear train can be turned by hand.

The Reclosing Circuit

The functions of the various components described previously are illustrated by Figure 3 which shows an elementary diagram of a typical circuit utilizing the new reclosing relay. The diagram shows the connections for an immediate initial reclosure followed by one or more delayed reclosures, with all contacts in the reclosing relay, identified by the device function number *179*, shown with the relay in its reset position. With these connections a total of six leads, including control power leads, will normally be required between the circuit breaker and the relay panel.

Immediate Reclosing Circuit

When the circuit breaker trips, the circuit to the closing relay is completed by the "*b1*" and "*LC*" switches of the circuit breaker *152* through the "preclosed" contact *179E1* in the reclosing relay and the *8-8C* contact of the control switch 101. Thus the initial reclosing time is determined solely by the tripping time of the circuit breaker, and the operating times of the closing relay *152X* and the closing mechanism. Operation of the auxiliary contact of the closing relay *152X* energizes the trip winding of the interlocking relay *179E*, which opens the "preclosed" contact *179E1* prior to the initial reclosure of the circuit breaker contacts, starts the timing motor through *179E3*, and sets up the reset circuit by means of *179E2*.

Reset Circuit

A short time after the start of the cycle, contact "*MN*" of *179* is operated by the single-ended cam "*E*" as described previously. If the immediate reclosure was successful, which will be true in the majority of the cases, contact "*a*" of *152* will be closed and the clutch release unit *179R* will be energized, through the *5-5C* contact of *101* and contact *179E2*. The reclosing of contact "*DE*" of *179* when the reset position is reached energizes the *179E* reset coil and the interlocking relay returns to its reset position. The reclosing relay now is ready to initiate an immediate reclosure in the event of a subsequent opening of the circuit breaker.

Delayed Reclosure Circuit

If the circuit breaker had tripped again after the initial reclosure the open "*a*" contact of *152* prevents reset of the reclosing relay, which will then continue to operate until the first delayed-reclosure point is reached as determined by the adjustments of the double-ended cams "*D*" on the front dial hub. The antipump relay, *179Z*, is picked up when the *b2* contact of *152* is closed so a subsequent operation of the "*AB-BC*" contact combination of *179* by one of the cam projections "*D*" completes the delayed reclosing circuit operating the closing relay *152X*. The antipump feature results from the response of the *179Z* relay to the opening of the *b2* contact when circuit breaker *152* recloses. Even a momentary opening of the *b2* contact causes *179Z* to drop out, breaking the seal-in circuit around the "*BC*" contact of *179* and opening the delayed-reclosure circuit. Thus only one reclosure of the circuit breaker is possible for each cam-operation of the "*AB-BC*" contacts of *179*. Since the control circuit involving the closing relay *152X* is frequently inherently pump-free, the *179Z* unit will usually be available for use in other capacities as desired.

A definite time interval after the operation of "*AB-BC*" by a cam projec-

Figure 2. Schematic representation of the operating mechanism in the new reclosing relay

tion "*D*", the opposite end of the same cam plate operates the "*MN*" contact of *179*. If the *a* contact of *152* is closed the circuit responds as described previously and the relay resets. Otherwise the relay continues through its cycle until the next delayed reclosure point is reached and the operations described previously are repeated.

Lockout

If none of the attempts to reclose the circuit breaker is successful the relay continues to operate until the lockout position is reached. This is indicated by the operation of contact "*GH*" of *179* by the auxiliary cam shaft, opening the motor circuit. This condition of the relay is indicated by the simultaneous operation of alarm contact "*JK-KL*" of *179*. In the lockout position contact "*NM*" of *179* is held closed by the projection of fixed cam plate "*F*", which is keyed to the dial hub, providing for reset of the reclosing relay after a successful manual reclosure of the circuit breaker.

Functions of Control Switch

The control switch designated as master element *101* continues to play an important part in the control circuit for the new reclosing relay. For example, with the relay in the locked-out position as described before, subsequent reclosure of the circuit breaker must be initiated by operation of switch *101* to the "close" position. The switch contact tabulation shown in Figure 3 indicates that when switch *101* is operated to the "close" position the circuit breaker is reclosed through contact *1-1C* but that the reset circuit of the reclosing relay is kept open by the *5-5C* contact until the switch is released and returns to the "normal after close" position. Thus reset of the reclosing relay is prevented if the circuit breaker is manually reclosed on a sustained fault.

The contacts of the control switch as connected in the elementary diagram prevent needless duty on the circuit breaker during a manual reclosure following servicing of the circuit breaker or line repair. For example if a circuit breaker is removed from service and grounded, and the grounding chains inadvertently left in position, the circuit breaker will be manually reclosed on a severe fault. It is desirable, if possible, to prevent the relay from initiating an immediate reclosure under these conditions. With the circuit shown, operation of the closing relay *152X* on manual reclosure trips the interlocking relay *179E*, blocking the immediate reclosing circuit before the circuit

Figure 3. Elementary diagram showing a typical application of the new reclosing relay

breaker can reopen, and starting the timing motor. The time interval before the first delayed reclosure provides ample time for the operator to react to the situation and return switch *101* to the "normal after trip" position. A successful manual reclosure following circuit breaker servicing or line repair will be followed after a brief interval by reset of reclosing relay.

Adjustment of Initial Reclosure

The new relay offers a degree of versatility in adjustment and application heretofore unavailable in motor-driven reclosing relays. The first requirement for a modern reclosing relay is that the initial reclosure shall be either immediate or delayed with the change from one to the other to be as simple as possible. In the new relay the type of initial reclosure is determined solely by the position of the preclosed contact *179E* in the reclosing circuit. This contact is shown in Figure 3 connected for immediate initial reclosure and its function has been described. For delayed initial reclosure the "preclosed" contact is connected in the position shown by the dotted lines. The closure of the *b2* contact of *152* following a circuit breaker outage will now energize the interlocking unit trip coil immediately, starting the timing motor and setting up the reset circuit. When the relay is first installed the position of the "preclosed" contact can be determined easily by the external wiring to the relay. A subsequent change from immediate to delayed initial reclosure can be accomplished either by a change in the external wiring of the "preclosed" contact or, as is usually more convenient, by removing the relay from its case and reconnecting the two leads from the *179E1* contact to a different pair of terminals. The contact leads are marked plainly and the terminals involved in the change are adjacent. No mechanical change is required in the relay unless different delayed reclosure intervals are desired, in which case a simple change in the setting of the cam plates carried on the dial hub suffices.

Co-ordination with Branch Circuit Fuses

On some systems involving multishot reclosing relays the main feeder is pro-

tected by a circuit breaker and branch feeders are protected by fuses. This economical means of sectionalizing a system requires that a fault on a branch feeder be cleared initially by the main circuit breaker tripped by a high-speed relay unit, and if the fault persists when the circuit breaker is reclosed that it be cleared the second time by the branch feeder fuse. To accomplish this the high-speed unit of the protective relay must be blocked following the initial tripout to allow time for the fuse to clear and it is advantageous that this be done by a contact in the reclosing relay. Contact *179E4* of the 2-position interlocking relay performs this function. This contact, which opens when the *179E* unit trips prior to the initial reclosure of the circuit breaker, is connected in series with the instantaneous contact of the protective relay to block instantaneous tripping of the circuit breaker on first and subsequent reclosures thus providing time for the branch feeder fuse to clear the fault rather than the main circuit breaker. Such a scheme now is extensively used so the inclusion of the blocking contact in the reclosing relay obviating the need for additional auxiliary equipment, either internal or external to the relay, is a distinct advantage. By proper co-ordination of the *179E4* contact with the spare cam-operated "*RS*" contact of *179* instantaneous tripping also can be blocked at other points in the reclosing cycle.

Reclosure Intervals

Opinion on the proper settings of a multishot reclosing relay is quite diversified, being influenced by the type of system and the condition of equipment involved, local meteorological conditions, and previous experience of the operating company. The design of the new reclosing relay is such that it can be adapted to meet the many different requirements for reclosing cycles. One object of the new design is to meet industry demand for a definite-time reset following any successful automatic reclosure of the circuit breaker. For this reason the relay is normally set for an immediate initial reclosure followed in 10 seconds by the resetting of the relay if the reclosure is successful, or if unsuccessful by a maximum of three delayed reclosures each in turn followed in 10 seconds by a similar attempt to reset the relay. With this normal setting the minimum interval possible between successive reclosures is 15 seconds, being determined by the cam arrangement necessary to obtain reset in 10 seconds following a successful reclosure.

It is recognized that unusual local conditions may sometimes render the definite-time reset feature unnecessary or possibly objectionable. By proper arrangement of the double-ended cams "*D*" and the single-ended cams "*E*" shown in Figure 2 and previously described, reset can be omitted after any reclosure except the final delayed reclosure. For example if delayed reclosures are desired at 15-, 30-, and 30-second intervals with reset after the final reclosure only, the following cam arrangement is required: One of the single-ended cams "*E*" is set to operate contact "*AB-BC*" of *179* at 15 seconds, the remaining two single-ended cams "*E*" still back-to-back are set to operate "*AB-BC*" 30 seconds later, and finally the three double-ended cams "*D*" with their projections back-to-back are set to operate "*AB-BC*" after another 30-second interval. Since the single-ended cam plates "*E*" do not operate contact "*MN*" there will be no possibility of the relay resetting until 10 seconds after the final reclosure.

By proper use of the single-ended cams to omit the definite-time reset after certain of the reclosures, intervals of less than 15 seconds can be obtained. It is in fact possible to set the relay for immediate reclosure followed by delayed reclosures at intervals of 5, 5, and 5 seconds, with reset of the relay 10 seconds after the final reclosure if any of the reclosures was successful. The definite-time reset which always follows the final delayed reclosure obviates the necessity for total reclosing cycles of less than three minutes.

Conclusions

The new relay includes several features previously not available in multishot, motor-driven reclosing relays. The definite-time reset feature following a successful reclosure will improve service by eliminating many unnecessary lockouts or delays in reclosure, and will allow more freedom in the selection of reclosure intervals. The preclosed contact for immediate initial reclosure will materially reduce the reclosing time and will be of value where ultrahigh speed reclosing is contemplated. An internal means of blocking instantaneous tripping on first and subsequent reclosures will simplify relaying of systems including branch feeders with sectionalizing fuses.

Apart from these material improvements the new relay will offer many advantages from the standpoint of versatility and ease of adjustment. The facility in selecting either immediate or delayed initial reclosure, involving no mechanical changes in the relay, will be especially valuable. The wide range of reclosing cycles now possible will permit universal application of the relay, combining in effect the advantages of the "single-shot" reclosing relay with the versatility of the multishot reclosing relay.

Discussion

R. J. Cooper (Georgia Power Company, Atlanta, Ga.): In order to supply good service economically, reclosing circuit breakers, co-ordinated into automatic control schemes, are a necessity. Operating companies are seeking improvements continually and are interested in the development of new equipment that is reliable.

As switchboard space is becoming more valuable, the size of the new recloser is very attractive. Blocking of instantaneous trip devices in protective relays after initial operation is being used extensively and we are glad to find consideration being given this feature by making it accessible if desired.

We now have in operation a number of reclosing relays which have the feature of resetting in a definite time (about 15 seconds) after a successful reclosure. Although some may be inclined to think it unwise to use such a circuit we have had no disastrous results in our experience which covers about 75 reclosers of this type over a period of 15 years.

Lower initial time for reclosing and elimination of lockouts due to second faults after the last time interval, are desirable. There are methods of accomplishing both of them with the present reclosing relays. Our experience with successful reclosing operations follows very closely the tabulation given by Mr. Goff. If the complete timing interval of the present relay is 90 seconds and the reclosing intervals 0-15-60 seconds, there is not much danger of lockout due to second faults after the last operation.

It is hoped that the designers have not sacrificed too much power in changing to the synchronous-type motor. Surplus power is essential to reliable operation under adverse conditions.

In our fast growing industry it is soon realized that the majority of our installations change so fast that they may be considered to be of a temporary nature. Any scheme that requires some special type of associated equipment for its operation is not desirable. Control switches with the contact arrangement shown in Figure 3 are very unusual in our estimation. In shifting equipment from one location to another this one requirement could cause considerable confusion on occasions.

We have in operation on our system approximately 750 reclosing circuit breakers. Of these circuit breakers approximately 325, mostly on the transmission system, are controlled by d-c operated reclosing relays. Our automatic substations require d-c reclosing relays in order to function after bus differential relay operation, or in some cases, transformer differential relay operation. The schemes always provide for one attempt to restore service from a preferred source after such an operation and our experience justifies the practice. Pneumatic circuit breaker operators, carriers for relaying or telemetering, or communication and control have all contributed to the necessity of station batteries. We tried a-c control schemes in an effort to economize and now are convinced that a light duty battery is the most reliable and economical source for automatic control. If it could be justified, all our principal reclosing schemes would be d-c operated and we are very concerned that the indications are that no d-c reclosing relay will be available. We prefer not to complicate a reclosing scheme or decrease its reliability by using inverters or vibrators or similar devices in order to use an a-c reclosing relay. Neither should it be necessary to add a "1-shot" type recloser in order to accomplish what we now do with one relay.

A survey of the users of the largest numbers of reclosing relays in our area indicates an increasing demand for d-c reclosing relays. We recognize the fact that there are improvements and advantages in this new relay but cannot help but feel that it is limited in its application whereas the present relay is universal.

H. C. Barnes (American Gas and Electric Service Corporation, New York, N. Y.): The announcement of the new reclosing relay described by Mr. Goff was welcome news to us since it came just as we had decided to try a single reclosure on distribution feeders of 13.2 kv and below.

Unless experience dictates otherwise it is planned to use instantaneous first trip, immediate reclose and subsequent time delay trip to lockout. This policy was predicated by observations that most faults which do not clear on the initial trip are permanent faults. These should be isolated by branch fuses after the immediate reclosure when the instantaneous trip relays are cut out. Further tripping and reclosing to clear the few remaining faults which may not be permanent does not seem justifiable when the increased damage in closing into permanent faults is considered. The ideal reclosing circuit for this arrangement would be one which permitted one immediate reclosure plus a realization of savings from eliminating the reclosing timer, yet readily adaptable to changing from immediate to time delay reclosure or additional reclosures if required. Relays previously available could be utilized to provide immediate reclosing at some economy but made the addition of time delay or additional reclosures cumbersome and expensive. The new relay will provide all of the versatility required plus the desirable feature of a definite short time reset after any successful reclosure. Since facilities for cutting out and restoring the instantaneous trip are incorporated in it, a reduction in cost should be realized by the elimination of the external relays previously used for this purpose. If the new relay is comparable in cost to the older *AC-1*, the over-all cost of the new reclosing equipment will be very little more than that of a single immediate reclosing scheme with subsequent time delay trip. Further economy may be realized by reduction in panel size and wiring due to the reduced size of the new relay and to the instantaneous cut out feature being internal.

Like most new devices this one may require modification to meet the rigors of operation. A great many distribution relays are installed in unheated outdoor cabinets mounted on the oil circuit breakers. The driving motor provided must be a much lower power device than the previous motor to permit the reduction in over-all size. Whether it will have enough torque to operate at temperatures well below zero after it has been subject to wear and atmospheric corrosion remains to be seen. Our experience with micro and miniature switches on such outdoor installations as transformer alarms has not been too good. Performance of the telephone relay contacts in the instantaneous trip circuit where heavy auxiliary relay contacts were previously used will need proving particularly since they will normally be closed and may not have had the benefit of recent wiping action.

The driving motor being synchronous apparently this relay is designed only for operation on alternating current. This should not be an insurmountable objection since there is not much point in closing a circuit breaker if no power is available. Distribution circuit breakers are usually closed from transformers and therefore have supply for the relay available. Where additions are being made to existing stations having battery closing, supply for the relay can be obtained from the potential transformers. This may occasionally require an additional potential transformer or throw-over devices. High-voltage transmission stations may require operation from bushing and capacitor potential devices when closing from a line after a complete station outage. Probably the extra burden can be handled by the bushing potential device but the volt-ampere and wattage requirements will need to be known to determine this. We assume that the component parts have sufficient insulation to withstand the fluctuations of the voltage output of these devices. Normally the relays could be supplied from the bus potential transformers, with throw-over to the line potential devices when the bus is dead.

Since we do not use the timer in high-speed reclosing of high-voltage lines the two or three cycles gained by the preset immediate reclosing feature does not at the present appear to be too beneficial. A similar reduction in the tripping time of low-voltage circuit breakers would do much more towards successful reclosing since conductor damage would be reduced, particularly when weatherproof insulation is required. The connection of the antipump relay *179Z* shown in Figure 3 is certainly desirable in that it operates on a drop out principle and assures antipump action even when closing into severe faults which cause the station control voltage to dip.

Occasionally a 6-minute timer is required to permit a complete testing sequence for a line having a series of automatic sectionalizing air break switches. We would be interested in knowing if gear pairs will be available to obtain other than 3-minute over-all time. It may be that the definite time reset feature will permit circuit changes which eliminate the need for the 6-minute timer requirement.

In conclusion we believe the developers of this relay should be congratulated on having taken a step in reducing the size and cost of control relaying and in applying telephone relays to combine several functions in one case. We have endeavored for some time to get around to developments in this direction but pressure of other work has prevented it. While passing of the old standbys like the HFA and HGA would be regrettable, considerable savings might be realized by packaging several telephone relays in one case with a flexible arrangement of connections and coil ratings to provide the hot line or bus indication, circuit breaker positioning indication, sequential relaying, and other auxiliary functions required in most automatic control circuits. Savings should result not only from the lower cost telephone relays but also in the elimination of relay cases, reduction of external wiring, and decreased switchboard space requirements. Circuit changes would not be as costly since they would mean mostly internal relay changes, thereby eliminating the need for panel rearrangement.

G. E. Brooks (Oklahoma Gas and Electric Company, Oklahoma City, Okla.): Announcement of a multishot reclosing relay with quick-reset features should be welcomed by many operating companies. The Oklahoma Gas and Electric Company has had in use on its system for more than ten years[1] a number of assembled reclosing relays in which are incorporated selective quick-reset features. There are now 32 circuit breakers controlled by these relays and there has never been an experience which would disfavor the quick-reset operation.

The new relay has, in addition to the fast-reset provision, a number of commendable features, such as compactness, relative simplicity and flexibility. Separate external terminals for the various elements of the relay, such as immediate reclosure, delayed reclosures, reset and motor circuits, permit flexibility for special applications. Perhaps as a result of compromise between simplicity and flexibility, certain operating disadvantages appear and are here briefly discussed.

Pump-free Circuit Breaker Operation

The new relay uses an antipump unit (*179Z*) to insure pump-free operation on delayed reclosures. This is a conventional scheme depending on sequential operation of timer-operated contacts, released by opening of circuit breaker auxiliary switch, *b2-152*. Pump-free operation on immediate

reclosure depends upon the action of an interlocking unit, *179E*, which is shown to be energized by a contact of the closing relay, *152 X*. This circuit will require some modification when applied to pneumatically operated circuit breakers having no closing relay contacts. Referring to Figure 3, operation of the timer motor for delayed reclosures is entirely dependent upon the action of the interlocking unit, *179 E*, during the interval in which the closing relay, *152 X*, is closed. For this reason and the one stated for pneumatically operated circuit breakers, it would appear desirable to use a contact of the mechanism pump-free relay, *152 Y*, to operate interlocking unit.

Experience has shown that a latch check switch, connected as shown in Figure 3, will defeat the purpose of the antipump relay, *152 Y*, in the mechanism in the event of latch failure. This fact is mentioned here only to emphasize the need for pump-free features in both the mechanism and reclosing relay. It would appear that the scheme employed here for delayed reclosing could be applied for pump-free immediate reclosing at an increase of two cycles in reclosing time. In many cases, additional delay would be permissible, and in some instances necessary, for successful immediate reclosing.

Selective Control of Immediate Reclosure

For reduction of hazard to personnel during hot-line work, it is often desirable to eliminate the immediate reclosure for a limited period. Unless a convenient means is provided for removing this feature (preferably by means of a panel-mounted control switch) the circuit breaker must be placed on manual control and an attendant provided during these periods, with instructions to close the circuit breaker on a "1-minute hold" schedule. To save the cost of such standby operators, the Oklahoma Gas and Electric Company has equipped several installations with switches for making the first or immediate reclosure inoperative. In some instances, this requires a major modification of the reclosing relay. Referring to Figure 3, such a choice of reclosing schedules may be made by selecting the solid or dotted connections for contact, 1-179E. This selection should be made external to the relay itself.

Control of Instantaneous Trip

Selective co-ordination of feeder relays with branch fuses, that is, co-ordination of fuses with relays for temporary faults and co-ordination of relays with fuses for permanent faults, has proved practicable and economical on many urban and suburban feeders. The effectiveness of the scheme in saving fuses during transient faults depends in part upon how low a setting can be applied to the instantaneous relays. Should the instantaneous relays be set too close to the feeder load current, operations may be expected when the circuit is energized following outages of more than a few seconds. This inrush and abnormal current, due to temporary loss of diversity of cyclic loads, can cause repeated operations or lockout of the feeder circuit breaker by the instantaneous relays.

On the Oklahoma Gas and Electric Company system these undesirable lockouts are prevented by modification of the instantaneous trip controlling relay.[3] This modification, which was made following the publication of the reference paper, is a scheme to provide supervision of the controlling relay by the instantaneous relays. By a series connection of normally closed contacts on the instantaneous relays the controlling relay, after having opened the tripping circuit, is prevented from timing out until all instantaneous relays have returned to normal. Normal position must be retained throughout the controlling relay's timing period before the tripping circuit for the instantaneous relays can be re-established. Thus, a load current of tripping magnitude upon circuit breaker reclosure will hold the instantaneous relays inoperative for the period of abnormalcy plus the timing period of the controlling relay. With this "super control" of instantaneous relays, momentary load currents may be allowed to exceed the relay setting without causing lockout of the feeder.

The new relay represents the first major improvement in manufactured reclosing relays in many years. As with other new designs, some modifications may be necessary to permit wider application. Any changes resulting in increased flexibility are certain to multiply its usefulness and defer its obsolescence.

C. A. Streifus (Ebasco Services Incorporated, New York, N. Y.): The relay described by Mr. Goff appears to be the most complete relay of its type for controlled immediate and delayed reclosing of circuit breakers as it has the required functional characteristics as well as being small, compact, and assembled in one case of conventional design.

Five years ago during proposed application of reclosing relays and observation of installed relays, our company reviewed the characteristics of available reclosing relays and wrote a series of desired operating specifications. None of the relays could meet these specifications without being modified or without addition of supplementary relays and timing circuits requiring considerable space. It is gratifying to note on comparing the specifications written at that time with those in the paper that this new relay meets them as well as having other desirable characteristics.

A most important feature of this new relay is its fast reset feature, similar to that in certain "1-shot" relays, except that there is provision for adjusting the time of reset. Fast reset prevents the circuit breaker from remaining open when a second temporary or arcing type fault occurs a few seconds after a successful immediate reclosure. This feature should raise further the percentage of successful immediate reclosures. On a number of occasions, the writer observed temporary type of faults occurring during the long reset period on installations where the reclosing relays did not have the fast reset feature. This caused the circuit breakers to remain open, thus the advantage of the first immediate reclosure was negated.

The feature of blocking the instantaneous trip circuit after initial circuit breaker tripout should be helpful in co-ordinating system relaying.

Circuit breaker duty and capacity should be reviewed for each application of relays with immediate reclosure and fast reset because of the relatively short interval possible between circuit breaker openings and resulting increase in duty caused by rapid occurrence of faults.

This new relay takes an important place in the series of developments pioneered by such men as E. E. George and J. T. Logan in the field of instantaneous reclosing of circuit breakers which is related to power system stability, reduction in length of outages of transmission and distribution lines, and broad problems associated with maintaining service to important loads.

L. E. Goff: The new reclosing relay described in this paper was developed to meet an indicated demand for a relay having features not provided in available multishot reclosing relays. It is gratifying to note from the comments of Messrs. Streifus, Barnes, Cooper, and Brooks that in general the goal has been achieved.

Cooper has pointed out that the choice of a synchronous motor makes the new relay unattractive for applications using d-c control voltage. The decision to use an a-c motor in the new relay was based on several factors. Small synchronous motors with relatively high operating torque and with insulation levels meeting switchgear standards are available. Universal types of motors with governors, providing comparable operating torque and insulation, are much larger and would not have permitted the desirable reduction in relay size. From all indications a dependable source of a-c control voltage is available on a large majority of circuit breaker installations. Where two or more sources of a-c control voltage are involved a simple throw-over scheme insures operation of the reclosing relays following a circuit breaker outage if voltage is available from any one of the sources. If all sources are dead nothing is gained by reclosing the circuit breaker. There is a distinct possibility that where station batteries are involved a throwover scheme would be required anyway to insure a dependable voltage source for the battery charging equipment. It should be noted that the low burden of the synchronous motor permits its operation from bushing potential devices.

Cooper suggests that the danger of unnecessary lockouts can be practically eliminated with available relays by using a short total time cycle and setting the final delayed reclosure close to lockout. While this is a possible solution, it does not prevent needless delay in initiating reclosure when two transient faults occur during the operating cycle of the relay. Furthermore, it places a limitation on the reclosing intervals possible for a given relay.

It should be emphasized that the new relay is not limited to application with the control switch shown in Figure 3. The control switch now considered conventional for automatic reclosing applications can be used, but because of the need for controlling the reset circuit of the new relay an additional

lead between the circuit breaker and relay panel is required. The new switch eliminates the need for this extra lead. The sequence of operation is the same in the new switch and it could be used if necessary as a substitute for the present one.

Barnes' proposed application of the new reclosing relay on distribution feeders illustrates very well its usefulness where it is desired to block instantaneous tripping after the initial tripout and prior to the first reclosure. The relay lends itself well to such applications where it may subsequently be desired to include several delayed reclosures, in addition to the immediate reclosure, at a later date, which is not possible with available single-shot reclosers.

The relay has been designed and has passed tests for starting and operation over the temperature range specified in the American Standards Association standards for switchgear relays, that is −20 to +40 degrees centigrade. Where temperatures lower than −20 degrees are encountered it is expected that heaters will be installed in the relay compartment.

The small switches used in this relay were originally designed for use in military aircraft and consequently met rigorous requirements, including satisfactory operation at temperatures well below those normally encountered on outdoor circuit breaker installations. It is interesting to note that the contact force of these switches is approximately 90 grams, or much higher than that of the usual auxiliary relay. It is felt that the telephone-type relay has already proved itself worthy of use in protective relays. In line with Barnes suggestion, groups of telephone-type relays in a single case have for a number of years been used in conjunction with standard carrier relaying equipment to perform various auxiliary functions, and their service record has been excellent.

As Brooks points out the circuit shown in Figure 3 depends upon an interlock contact of closing relay *152 X* to energize the *179E* "trip" winding and provide pump-free operation following immediate initial reclosure. On pneumatically operated circuit breakers there is of course no such contact available, so other means must be found for energizing the *179 E* coil. This question has already been considered and a circuit worked out for applying the relay on pneumatically operated circuit breakers, employing the *179Z* unit in conjunction with a seal-in resistor.

It is true that starting of the timing motor to initiate delayed reclosures is dependent upon the successful operation of interlocking unit *179E* during the interval in which closing relay *152 X* is closed. However, the operating time of *179E* is less than one cycle, whereas the *152 X* relay will remain picked up for from 10 to 15 cycles, so there is a wide margin favoring successful operation of the unit.

Over-simplification of the schematic diagram in Figure 3 has evidently caused confusion as to the intended connections of the seal-in contact of *152 Y*. This contact will seal-in around the "*LC*" and "*b*" switches of the circuit breaker and hence will provide satisfactory pump-free operation.

Brooks also has pointed out a potential difficulty in blocking the instantaneous trip circuit when the reclosing relay has the quick reset feature. If high-dropout instantaneous relays are used to permit a setting close to normal load current, they will probably pick up on inrush following a successful delayed reclosure and may still be closed when the reclosing relay resets. This would cause an unnecessary tripout since the instantaneous trip circuit would be restored when the reclosing relay reset.

The trouble can be avoided by either of two methods. A normally closed contact of the instantaneous relay for each phase could be connected in series in the reclosing relay motor circuit. Thus the reclosing relay will not run following a successful reclosure until inrush current in each phase has fallen below the dropout point of the respective phase relay. This scheme will not prevent an unnecessary tripout if the circuit breaker is successfully reclosed manually with the reclosing relay in the locked out position, since the relay would then reset as soon as the manual switch was released, reinstating the instantaneous trip circuit. An alternate scheme using a simple hinge-type auxiliary relay in conjunction with normally open contacts of the high-dropout instantaneous relays will prevent this trouble also. The normally open contacts of the three instantaneous relays would be connected in parallel to operate the auxiliary relay if any of the instantaneous relays were picked up. A normally closed contact of the auxiliary would be connected in the motor circuit and another in the reset circuit of the reclosing relay. This will prevent the timing motor from operating following a successful circuit breaker reclosure until the instantaneous relays have all reset, and will also prevent reset of the relay from its locked out position until the same relays have dropped out following a successful manual reclosure. Of course if the motor and reset circuits of the reclosing relay are both operated from the same a-c supply, the same thing could be accomplished by connecting series normally closed contacts of the instantaneous relays in the common lead.

Ice Testing of Outdoor Disconnecting Switches to Simulate Field Conditions

J. B. OWENS
ASSOCIATE AIEE

THE "ice storm" is one of the major difficulties encountered in the operation of electric power systems. Under certain atmospheric conditions a deposit of hard clear ice can build up in a few hours to a thickness which causes overhead lines to fail, and which renders the operation of outdoor switching equipment very difficult. To overcome operating difficulties under these conditions, many ingenious outdoor switches which employ some auxiliary blade motion to break ice have been developed. This blade motion has been accomplished by a great variety of mechanisms, and doubtless many others will follow.

The testing of these outdoor switches to determine the effectiveness of their ice breaking mechanisms has long been a problem to both switch manufacturers and power system engineers. In most locations, severe ice storms occur infrequently so that testing under natural conditions becomes impractical. Thus the problem arises of producing artificially the thickness and density of ice coating which occurs in nature. If any outdoor switch were frozen in a giant ice cube large enough to contain the entire switch, obviously it would be inoperable. Therefore, testing must be done with an ice thickness comparable to that actually encountered in service. Also the strength and tenacity of an ice coating varies considerably with variations in the air temperature, water temperature, and rate of application. These factors must be controlled carefully to obtain proper results. It is the purpose of this paper to describe an ice test which produces conditions comparable to those obtained in the field, and to describe the design features of a switch which can be operated easily under severe icing conditions.

Formation of Ice

The weather conditions which most often produce severe ice storms are those which prevail when a warm air mass has overrun a cold air mass so that rain is falling through air which is slightly below freezing. Such warm fronts usually extend over a considerable area producing wide precipitation belts, and these fronts are slow moving compared to cold fronts so that the rain may persist for a number of hours.

Under the conditions described, the falling water is cooled by evaporation and by its travel through the cool air mass so that it freezes almost instantly upon contact with objects on the earth. When the temperature of the air near the ground is only a few degrees below freezing, the ice which is formed is hard and clear and free from the inclusion of air bubbles. This is the kind of coating which creates the greatest difficulty in switch operation.

In general, ice which is formed at very low temperature (below 15 degrees Fahrenheit), and ice which is formed from moisture condensing from the air onto cold surfaces has a very porous and weak structure. Such ice is called rime ice, and is characterized by a white rather than clear appearance. This appearance is a result of the many small air spaces included in the structure. A good example of rime ice is the formation on the cooling coils of a home refrigerator.

It has been found that if switches are cooled to temperatures below 15 degrees Fahrenheit and are sprayed with a fine mist, a coating of rime ice is deposited. This coating is broken very easily even when the thickness is great, and such a test is not a real measure of the ice breaking ability of the mechanism.

A test which has been found to give consistently a clear hard ice deposit is as follows:

1. Assemble all poles and mechanism of the switch on a structure to permit normal operation. The operating pipes may be shortened to suit space requirements.

2. Clean all traces of oil or grease from all outside switch surfaces. Even thin films of oil or grease prevent ice from adhering to the switch and greatly change test results.

3. With the switch blade in the desired position, lower the air temperature to 35 degrees Fahrenheit, and then spray the switch with water which has been cooled to approximately 35 degrees Fahrenheit. This spray should be arranged to simulate a general rain and not a fog or mist. The water should fall from above and at an angle not exceeding 45 degrees from vertical. The location of the spray should be such that the pole units and entire operating mechanism are covered with a uniform rainfall.

4. After the rain is started, the air temperature should be lowered at the rate of approximately 3 degrees Fahrenheit per hour to a final temperature of 25 degrees Fahrenheit. This causes the switch to be sprayed for an hour before freezing temperature is reached, and the switch is thoroughly wet when freezing begins. The amount of water supplied should be such that ice forms at the rate of about 1/4 inch per hour.

5. Continue the spraying while holding the air temperature between 25 and 30 degrees Fahrenheit until a deposit of ice one inch thick has formed.

6. After the ice has been deposited, the switch may be operated and the operating effort noted.

Typical Test Arrangement

A laboratory setup to make the test just described is shown in Figure 1. The switches which were tested were two 15-kv 400-ampere 3-pole manually gang

Paper 30-239, recommended by the AIEE Switchgear Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 6, 1950; made available for printing August 31, 1950.

J. B. Owens is with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

The author wishes to acknowledge the contributions to these tests made by W. R. Smith, George Lambert, and other engineers of the Pennsylvania Power and Light Company.

Figure 3 (above). Close-up view of final ice coating showing the exceptionally heavy clear ice coating

operated air switches with offset torsional mechanisms.

Figure 1 also shows the pipes which comprised the spraying system to create the rain on the switches. These pipes were located at the level of the switch bases, and were supplied with water cooled to 35 degrees Fahrenheit by being circulated through a coil embedded in dry ice. The pipes were 1/2-inch thin-wall brass tubing and were drilled with 0.028-inch diameter holes on 9-inch centers to release the spray. The water pressure was adjusted to cause the streams to rise about six feet into the air before falling onto the switches. With this particular arrangement $1^1/_2$ gallons of precooled water were sprayed per hour per square foot of area sprayed to cause the ice to form at the desired rate. An air blower in the cold chamber served to agitate the rainfall to assist in uniform distribution over the switch.

Figure 2 shows the arrangement used to precool the water for the rain. Tap water was used, and it was cooled by being passed through 120 feet of 1/2-inch copper tubing wound into a coil surrounded with dry ice. The coil was placed in a micarta tube approximately 16 inches in diameter and 30 inches long. Dry ice chips were packed in the center of the coil. The output water temperature was controlled by varying the amount of dry ice used, and by varying how closely the chips were packed.

Figure 3 shows the clarity of the coating on the test switches after ice has been deposited. After the switches were operated, they were placed in an intermediate position between open and closed, and the photograph of Figure 4 was taken. This shows how the blade twisting motion, and the flexing of the jaws have cleared the ice from the contacts.

Measurement of Ice Thickness

One of the chief problems in making tests of this kind is that of knowing when the right quantity of ice has been deposited. Many utility company specifications have been studied, and "one inch of radial ice" is most commonly specified for testing of this kind. A final thickness of one inch is suggested as a standard for testing since this amount is rarely exceeded in service in the continental United States. However, ice does not form with uniform thickness over all switch surfaces, and the further problem arises of determining the correct place to measure the ice.

Figure 2. Dry ice chamber for precooling water to spray switches

On a power transmission or distribution system which has been blanketed with an ice storm, the ice of greatest interest, and that which has the most nearly uniform thickness, is that formed on horizontal overhead conductors. Around these circular conductors ice is formed with approximately uniform thickness. A measure of the radial thickness of the coating on a horizontal conductor is a fair measure of the severity of the storm.

On outdoor air switches, ice forms much more rapidly on some surfaces than others. Therefore, a measurement of the ice at any one place on the switch will probably not give a fair measure of the severity of the coating. One method which has given good results is to mount a piece of copper cable so that it is horizontal and receives the same rainfall as the switch. A measurement of the ice thickness at the top side of this conductor can be taken as an index of the thickness of the ice coating.

Many of the outdoor air switches now on the market have a single blade of circular section. A measure of the ice on the top side of the blade of such a switch in the closed position compares closely with ice on a circular conductor, and can be used as a measure of ice severity.

Figure 4. Close-up view of switch pole units with each switch in an intermediate position after being operated

Design Features of an Ice Breaking Switch

In developing the ice tests described in this paper, a great number of tests were made on a variety of switches, and certain desirable features of design for ice breaking switches were determined.

An ideal design for an air switch to operate when covered with ice, is one in which all moving parts are totally enclosed and cannot accumulate ice. Obviously, a practical design cannot enclose the blade and break jaw, and there is a need for auxiliary blade motion to break ice on the jaw. Many such motions have been devised; one of the most popular being a blade twisting motion that takes place before blade rise begins. In general, this motion is very effective in clearing the jaw of ice, provided the mechanism used to obtain the blade motion does not itself become fouled with ice It is possible to design a mechanism which is itself entirely enclosed and protected from icing; such a mechanism has been described by H. W. Graybill and J. S. Ferguson.[1] This mechanism is employed in the switch described here. Thus the first feature of switches designed to work under ice conditions should be an enclosed blade actuating mechanism.

The tests which have been described revealed further that the hinge-end contact was another source of difficulty under ice conditions. Switches were tested which had jaw contacts at the hinge, similar to those used at the break end. These hinge jaws gathered ice and increased the initial effort required to start the switch moving. Switches with totally enclosed hinge contacts showed a considerable reduction in operating effort under ice conditions.

It also was made apparent during the testing of these switches that adjacent switch parts with relative motion should be widely spaced. Any flat surface which was required to move with respect to a closely-adjacent parallel stationary surface was particularly troublesome. Ice bridging between these surfaces was very difficult to break. Therefore, a third feature of ice breaking switches is the freedom from closely spaced parallel surfaces which have relative motion during switch operation.

Figure 6 shows a pole unit of a switch which was designed to operate under severe ice coatings, and which incorporates all of the features found desirable in the testing program.

Summary

At the present time, there is no standardized method of testing outdoor air switches to evaluate their performance when covered with ice. A careful study has been made of the problem of produc-

Figure 5 (left). Test setup for 115-kv 1,200-ampere switches

Figure 6 (below). Pole unit of a switch especially designed to have good performance under heavy ice coatings

ing ice in artificially cooled rooms which corresponds in density, and strength of bonding with that encountered in service. The essential elements of a testing procedure to give the desired results are as follows:

1. Assemble a complete switch for normal operation, and clean all traces of oil or grease from switch surfaces.

2. Lower the air temperature to 35 degrees Fahrenheit and start a general rain of water which has been precooled to 35 degrees Fahrenheit.

3. After the rain has been started, lower the air temperature approximately 3 degrees Fahrenheit per hour until a final temperature of 25 degrees Fahrenheit has been reached.

4. Continue the rain with the air temperature at 25 degrees until an ice thickness of one inch has been reached on the top of the switch blade or on a horizontal conductor receiving the same rain as the switch.

5. Operate the switch and note the operating effort.

During the testing of many switches using these specifications, certain important features of design for ice breaking switches were determined. These features are as follows:

1. An auxiliary ice breaking motion should be imparted to the blade before blade rise begins. The mechanism which imparts this motion to the blade should be enclosed and protected from ice accumulations in both open and closed positions.

2. The hinge-end electrical contacts should be protected from ice accumulation.

3. Closely spaced parallel parts with relative motion during switch operation should be avoided.

It is suggested that the testing method developed be considered as a standard procedure for outdoor switch testing.

Discussion

C. S. Beattie and **S. C. Killian** (Delta-Star Electric Company, Chicago, Ill.): The ice tests described in the paper are interesting and a big step toward a possible standard for testing which might be used for comparing the ice breaking ability of the many types of outdoor switches now offered by various manufacturers.

Laboratory setups without the exact control described in the author's paper have been used for a good number of years and have served the purpose of securing valuable design data in connection with outdoor disconnecting switches. The test specifications proposed will produce ice and sleet of certain characteristics but operating experience indicates it is extremely difficult if not impossible to duplicate the work of nature during certain sleet storms. It also has been proved that the thickness of the ice or sleet coating bears no definite relation to the operating effort required to break a switch loose under certain sleet conditions. Very thin coatings under some conditions appear to be much more troublesome than ice coatings several inches thick.

Laboratory tests although valuable for comparative purposes are no insurance that the equipment will be sleet- and ice-proof over long years of service and under all conditions of corrosion, type of operating mechanism, and method of mounting. The tests described are not difficult to pass using a modern corrosion-free switch with a simple short operating mechanism.

The author stresses the importance of enclosed hinge contacts. The introduction of hinge contacts on rotating insulator vertical break disconnects is a direct result of the trend to eliminate flexible shunts on outdoor switches.

Assuming that the break contact is the best design possible, it is only good sense to attempt to use this design at the hinge contact also. If the over-all switch design does not lend itself to this, some other contact must be used at the hinge. Since this is an entirely different contact design it can be so constructed as to be covered. However, by putting it into a limited space, the rugged and reliable break contact design is lost and a multiplicity of small contact springs, small bridging members and current carrying pins must be used. Current interchange surfaces also are needlessly increased. Furthermore, this design does not lend itself to use in high capacity switches such as 4,000 and 5,000 ampere.

Too often the cover over the hinge contact creates much more of a hazard than the contact itself. This large cover area must move in relation to the remainder of the switch and under ice this will increase the possibility of immobility.

There is small difficulty in making a switch ice and sleet proof in a design using identical break and hinge contacts since inherently greater mechanical advantage is available at the hinge because of the shorter lever arm from the blade driving mechanism to the hinge contact as compared to the lever arm required at the jaw end. The ease of inspecting or replacing either blades or contacts is a decided operating advantage, best realized by the use of a properly designed open hinge contact combined with a powerful factory-sealed blade driving mechanism.

R. M. Smith (Railway and Industrial Engineering Company, Greensburg, Pa.): We wish to congratulate Mr. Owens for his work in bringing before the Institute a subject which needs additional attention and discussion. While the matter of ice testing of switches has received consideration throughout the past years, there has been no concerted effort to standardize laboratory tests in order to obtain a comparison of results and to more nearly simulate actual conditions met with in service.

We note that as a result of the testing of switches under icing conditions, Mr. Owens concludes that the switch should have an "auxiliary ice breaking motion" before the blade rise begins. We are glad that Mr. Owens concurs with our findings, for C. G. Koppitz of the Railway and Industrial Engineering Company first developed a switch of this nature about 25 years ago, and this construction, popularly known as the tail-twister design, is now practically a standard for the industry.

We concur with Mr. Owens' conclusions regarding the generous spacing of parts in relative motion during switch operation. Also, our present switch construction encloses the hinge end contacts, and we consider this most important for a good ice breaking switch. In fact, our tests indicate that the effort required to move the various bearings on the switch can become a major portion of the total effort and requires special attention. For example, in our construction, the blade itself has only one exposed bearing where ice must be sheared, whereas some constructions current today have two exposed bearings, and, in some cases, even four.

In the same manner, the bearings carrying the rotating insulator stack may add considerably to the operating effort, when they are heavily coated with hard ice. We have always used the construction shown in Figure 1 of this discussion in which a sealed, dry, ball-bearing construction is used. The sealing consists of a neoprene gasket, running on a bronze machined race, so as to give a weatherproof seal. Tests indicate that this bearing, under dry conditions, requires about 25-inch pounds to cause it to rotate. When fully sealed and dry but covered with 5/8-inch of hard ice, it requires 136-inch pounds to shear the ice. However, when

Figure 1. Grease-less sealed switch bearing

3. Synthetic rubber gasket for weather seal
4. Adjusting and take-up nut
5. Galvanized forged steel rotor

$1^3/_4$ ounces of water are deliberately introduced inside the bearing and frozen, with no external ice, it requires from 600- to 1,000-inch pounds to rotate a single bearing. This illustrates the advantage of the dry, sealed, ball bearing, and also shows that a good ice breaking switch must have attention directed to all of the components and not only to the current carrying path.

Mr. Owens describes a hood or cover over the hinge and rear electrical contact, which appears to keep the water out of the inside when mounted in the upright position. We would assume, however, that with the switch mounted in the inverted position, it would be most difficult to keep water from entering this cover since it would then be mounted in the opposite position and water would tend to run into this pan around the bearing of the rotating insulator.

W. B. Morton (Pennsylvania Power and Light Company, Allentown, Pa.): The tests and procedures covered by this paper were promoted at the instigation of engineers of the Pennsylvania Power and Light Company, as a result of years of investigation into the vagaries of sleet formation, and much experimentation with various kinds of sleet-melting devices on a transmission system covering 9,500 square miles of territory that is highly vulnerable to sleet formation. It was discovered in these investigations that no disconnecting switches on the Pennsylvania Power and Light Company system, of any manufacturer, were entirely immune to freezing fast and becoming inoperable in service, despite elaborate ice testing by the manufacturers' laboratories.

This experience led to one obvious conclusion that current practices were inadequate to produce the conditions of ice formation actually experienced under field conditions. Thus a new concept of ice freezing technique was developed and promoted by Pennsylvania Power and Light Company engineers with results outlined in the paper.

The paper should lay more emphasis on the important fact that this new concept of ice testing differs from all previous ones in that it is based on a high-temperature slow-freeze, in contrast to the previous universally accepted, but erroneous, thinking that low temperature quick freezing is a true criterion of field conditions. Moreover, an important consideration early discovered in the Pennsylvania Power and Light Company investigations, that is not pointed out by the author, is the necessity for thoroughly spraying the equipment for at least an hour prior to the test, as a sleet storm is usually preceded by rain before reaching the sleet stage, to insure that water has penetrated all crevices and interstices, which penetration under field conditions is one of the major causes of some switch failures that are not detected in the obsolete laboratory "quick freeze—low temperature testing."

The paper also should emphasize that the needed revisions to the AIEE standards for disconnecting switches should require that they be ice tested in both open and closed positions.

J. B. Owens: The testing program which provided the information for this paper revealed that in general a switch which was frozen in the closed position required a higher operating effort than the same switch frozen in the open position. This was a result of ice on the break jaw and arcing horns interfering with starting the switch toward the open position. With a well designed switch the closing operation could be started easily and the inertia of the parts provided enough impact to shatter ice on the jaw to allow full closing. In the evaluation of a new design, however, it should certainly be tested in both the open and closed positions.

This paper has not attempted to describe all the details of design which are required to make a good ice-breaking switch. It has only pointed out salient features which contribute to a good ice-breaking performance. To produce an outdoor switch to operate satisfactorily under all conditions requires careful attention to many details such as proper bearing design, complete sealing of ball bearings, and proper design of switch parts to prevent water accumulation with any switch mounting position. These details have all received proper attention in the switch shown in the paper.

The interest which has been shown in the development of these tests indicates a real desire for standardization of ice testing procedures.

It is hoped, therefore, that this paper will provide a starting point from which procedures can be devised which will be satisfactory to all concerned.

A Simplified 48-Channel Carrier Telephone System

L. G. ERICKSON
MEMBER AIEE

Synopsis: This paper describes a 48-channel single side band carrier system which provides toll quality telephone transmission bands with exceptional simplicity and dependability of equipment. Through the use of a novel frequency translation pattern, speech bands covering the range from 200 cycles to 3,500 cycles are secured at 4-kc channel separation without resort to crystal filters. In this system, improved translating modulator techniques and other advanced features reduce the number of vacuum tubes to a minimum while achieving exceptionally high performance standards, stability, and ease of maintenance.

Prior Art

THE single-side band suppressed carrier method of deriving multiple communication channels from a common transmission medium is now almost 40 years old. The solutions to the basic transmission problems were set forth by E. H. Colpitts and O. B. Blackwell in a paper, now classic, which appeared in 1921.[1] The first systems to provide good telephone circuits by this method came into widespread use about 1927. From this point on, advances in the art were rapid with large scale installations of 3-channel systems coming to be a factor in trunkline telephony about 1933. By 1938 the 12-channel systems for open wire and cable, those recognized by communication engineers as the *J* and *K* systems, had attained a high degree of development.[2,3,4] Relatively soon thereafter the coaxial carrier system, designated as type *L*, was developed to provide really large numbers of channels on a common transmission circuit.[5] Further developments in multiple-channel communication, both delayed and accelerated by World War II, are the present-day introduction of radio relaying, and long strides in the direction of simplification and reduction in carrier equipment cost.

The same general pattern is traceable through the history of progress of many technological advances in all fields. First, the invention is shown to be of utility, though exhibiting perhaps no marked operational or economic advantages. Next, its performance is improved, sometimes at inordinate cost, creating a demand for the higher standard. Then comes the protracted period of simplifying designs while at the same time improving dependability and reducing maintenance cost, finally realizing the full advantages which the early inventor had dreamed for the new method. The advent of a multiple-channel telephone carrier economically applicable to circuits as short as 20 miles realizes an ambition set many years back.

The Present Contribution

The communication industry now is reasonably well standardized on 4,000-cycle separation for telephone channels having the transmission quality attendant to a bandwidth of at least 3,000 cycles. To achieve such spectrum economy and performance in systems having many bands translated to positions above one another, relatively costly crystal filters were brought into being. These are widely used in many systems currently being installed. The design of a system which affords 3,400 cycles of bandwidth per channel while employing relatively simple and inexpensive inductance-capacity filters marks a definite advance, particularly for short-haul wire line and radio applications. It is noteworthy too that while earlier multiple channel systems employed on the average 12 electron tubes per 2-way conversation circuit derived, the latest technologies reduce the tubes to approximately five per 2-way circuit.

General Description and Theory

Communication literature discloses the single side band suppressed carrier principle so well, both in theory and application, that a detailed explanation here is undesirable. However, in the interest of making this paper self-sufficient, a very basic concept of the end result of single side band modulation is justifiable. The intelligence frequencies essential to the reproduction of good telephone conversation may be regarded as a heterogeneous, though, of course, a discrete mixture of sinusoidal components within the range from 200 cycles to 3,500 cycles. A balanced modulator which suppresses both the original intelligence frequencies and the carrier frequency, followed by an appropriate filter which passes only one complete set of beat notes between those intelligence frequencies and the carrier frequency, is in fact a frequency translating system.

A plot of the currents resulting from two tandem stages of single-side-band modulation, as shown in Figure 1 serves to illustrate in an extremely simple manner. Graph "A" presumes the instantaneous speech current to be a sinusoidal wave of 1,000 cycles. The upper side band after modulation by 8,000 cycles is the 9,000-cycle current of "B." If "B" is passed through a second stage of modulation, the carrier of which is still higher, the single-side-band current again is a sinusoidal wave 9,000 cycles removed from the new carrier as shown by "C." Two quite reciprocal translations will bring back the original input intelligence

Paper 50-240, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23-27, 1950. Manuscript submitted July 26, 1950; made available for printing September 27, 1950.

L. G. Erickson is with the Leakurt Electric Company, San Carlos, Calif.

Figure 1. Translation of speech currents

frequency, in this case the 1,000-cycle sine wave. If the original speech wave is a frequency other than 1,000 cycles, the location of the frequency which represents it after each translation is different by an exactly corresponding amount. If the original wave is of a different amplitude, then the side-band wave which represents it has a corresponding different amplitude.

Fidelity of reproduction of the complex wave of speech depends upon the degree of amplitude linearity of the translating device, and upon the absence of extraneous currents introduced by the process. Thanks to current communication engineering practices, these translations now are accomplished in almost any desired number, with little, if any, detectable distortion of the original intelligence wave form. Of great practical significance, these translations are accomplished in the equipment being described largely by inert devices having a very high degree of stability and indefinite life.

The prime requirement of the filter employed to separate the desired group of side bands from the undesired group is that it shall adequately suppress the latter group. The secondary requirement, though still an important one, is that it shall pass those frequencies representing that side band which is to be used with a minimum of difference in attenuation and a minimum of relative phase shift. "Adequately," of course, is a matter of degree, but if the unwanted group is allowed to go over the transmission circuit, the result is interference to some other channel of the system, the magnitude of which is directly proportional to the unsuppressed voltage. High-grade telephone circuit operation, then, requires that the unwanted "image" be suppressed at least 55 to 60 decibels with respect to the wanted group.

When we consider the first translation from the speech frequency it becomes evident that the filter employed to select the wanted side band must offer a high degree of attenuation to the lowest frequency of the unwanted side band. The "guard" band, or the interval in which the filter characteristics must change from very low attenuation to very high attenuation is then twice the lowest frequency in cycles to be transmitted over the channel. Since we are going to stack channels later at 4-kc intervals, it also is necessary that frequencies beyond the high end of the pass band be attenuated greatly since otherwise they would be detected as low frequencies in an adjacent channel. This means that if we are to transmit frequencies of 3,600 cycles over a particular channel, the characteristics of the band pass filter we are considering also must change from very low attenuation to very high attenuation for a change of frequency equivalent to 3,600 cycles in one channel to a frequency of 200 cycles in the channel immediately above. This would correspond to a guard band required on the "high" side of 600 cycles. This performance is attainable at reasonable cost only at relatively low carrier frequencies.

Translation System of the Type 42

This new 48-channel carrier telephone system employs two successive stages of modulation to accomplish frequency translations for each channel. With this method the first stage of modulation utilizes an 8-kc carrier frequency, and the upper side band is selected for transmission. Regardless of its future frequency allocation, each channel is positioned initially at an intermediate frequency band between 8 and 12 kc. Filters having very

Figure 2. Translation pattern and channel allocation chart

Figure 3. Functional diagram of typical channel

desirable characteristics can be built in this range of frequencies, and since one filter only need be designed for all channels, great care can be taken to obtain optimum characteristics.

Since the filters required in the subsequent stage of modulation will have broader pass band characteristics, the pass band of this first filter will determine to a large degree the response characteristic of all channels derived by this method, and this response characteristic is remarkably uniform from channel to channel.

Subsequent to this initial modulation, higher frequency modulators are used to accomplish frequency translations between the intermediate frequency band and the final line frequencies of 12 to 204 kc. In this way up to 48 channels may be assembled on 4-kc spacing with guard bands of only 600 cycles between channels; yet the high frequency modulators and filters only need to meet the design requirements for a system having a guard band of 16 kc between channels.

The translation pattern of the type 42 system is easiest explained with reference to Figure 2, the channel allocation chart. The first two channels are moved upward to their line frequency location by a conventional single stage of translation which

Figure 4. Transmission characteristics of intermediate filter and typical channel filter

Figure 5. Typical modulator-demodulator (modem) panel

needs no further explanation. Excepting these first two channels, each voice band is first modulated to an intermediate position between 8.2 to 11.5 kc. At this location, the unwanted image is easily suppressed without resort to crystal filters. A second translation for each channel is performed by carriers each 8 kc removed from the ultimate line-frequency location. After this translation, the unwanted image is at least 16.4 kc removed from the wanted sideband, and again the suppression is accomplished with relatively simple inductance-capacitance filters. Avoiding block translation such as is employed in many systems, the equipment elements have a great similarity, and the system has an unusual degree of simplicity.

Equipment Details

In order to conform with accepted carrier system standards and for mechanical convenience, channels of the type 42 system ordinarily are assembled as required, each rack having a normal capacity of 12 channels. The functions of the channel equipment can best be understood by reference to Figure 3. Each modulator-demodulator or modem unit contains all the filters and electronic equipment required in one voice channel for both the outgoing upward-translations and the incoming downward-translations. The outgoing speech currents from the external hybrid transformer first encounter a 3.6-kc low-pass filter. The output of this filter is delivered to a double-balanced modulator driven by an 8-kc oscillator. The wanted side band, included between 8.2 and 11.6 kc is selected by an intermediate frequency filter which has a substantially uniform response characteristic throughout its required pass range and which rejects the image frequency of the modulation by at least 55 decibels. The identical filter is standard in all channels of the system. Its transmission characteristic in large measure determines the over-all response characteristic of the carrier channel. The wanted sideband is delivered to the second modulator driven by a precision oscillator which locates the channel in its final line-frequency position. The output of the high-frequency modulator is fed through an attenuator to the final channel filter. Typical characteristics of the modem filters are shown in Figure 4.

The crystal diodes used in the modulators have a remarkable degree of stability, permitting accurate balances for the suppression of both the carrier and the original voice-frequency input signal. Their freedom from noise allows both translations to be accomplished without the amplifiers customarily employed to recover power level between successive stages. The modulator circuit is so arranged as to minimize the effect of the back-voltage-versus-current characteristic of the diodes. Thus a current linearity corresponding closely to a true off-on switching device is achieved without resort to an inordinately high carrier supply voltage.

It will be noted that from the outgoing side of the 4-wire terminating set to the output of the channel filter no tubes are involved except those in the translating oscillators. It is appropriate here to point out that the same oscillators are used to drive both the sending modulators and the receiving demodulators. On the incoming side, the diagram of the filtering and translating equipment is practically a mirror image of that on the outgoing side with no tubes utilized until the signals, at voice frequency, are finally amplified just before they are delivered to the receiving branch of the hybrid-coil 4-wire terminating set. The frequency translations, of course, are a complete reversal of those on the transmitting side. The intermediate frequency filters and the voice frequency filters are identical on the two sides. The high-frequency channel filters may or may not be identical, depending upon

Figure 6. Twelve-channel group assembly

whether the equipment has the channel allocations required for 4-wire working on wire lines or radio, or the allocations used for 2-wire working on wire lines.

A typical modem panel is shown by Figure 5. Filters, modulators, and the final voice-frequency receiving amplifier are constructed as separate subassemblies to the modem panel. This component design makes for ease and economy in the construction of modem units for different line frequency allocations. The compact modem assembly makes it a simple matter to add channels as needed to a group initially installed with only as many channels as needed.

A typical 24-channel assembly is shown by Figure 6. Each rack normally mounts 12 modem panels although this particular picture shows only nine. Normally three more would mount above the five shown on the rear of the rack.

Figure 7. Transmission characteristic of typical single channel and five tandem patched channels

A channel level-adjustor on the incoming side is located adjacent to a master jackfield for the 12-channel bay assembly. This jackfield gives access to the 2-wire side of the 4-wire terminating set and to the sending and receiving loops of the 4-wire side. The 4-wire terminating sets, the fuses, terminal blocks and other common equipment are mounted at the top of the 12-channel assembly. Shown above the jackfields are the pilot regulators incorporated when 2-wire operation of a 12-channel system is required.

Each rack is provided with a transmitting and receiving amplifier for the group of 12 channels, which, in turn, are multipled into 24-, 36-, or 48-channel systems through grouping filters and differential transformers to the common transmitting or receiving lines.

Performance

Any multiplexing system designed to provide a large number of channels for either record or voice communication must meet a number of rather exacting performance requirements. In the first place, it must be thoroughly dependable. Modern-day standards require that lost time due to equipment failures shall be an exceedingly small per cent of total operating time. Causes for such system interruptions due to equipment must easily be determined and located. Apparatus failures which can interrupt all channels simultaneously must be reduced almost to the vanishing point. The independence of the 12 channel groups of the type 42 and the independence of the individual channels within a group contribute materially to the dependability sought. With the number of electron tubes in the equipment held to a minimum, interruptions due to tube failures are correspondingly reduced.

The electrical performance requirements can be listed very briefly as: freedom from frequency shift; uniformity of attenuation within the derived voice band; low wave-form distortion within the voice band; stability of power level delivered by the voice band; low residual noise level; and freedom from cross modulation between bands.

A little consideration of the theory of the frequency translation principle brings the realization that the oscillators used for those translations should not drift with respect to one another. Changes in the relative frequency of the oscillators used to step the audio signal up to its intermediate frequency position at the sending end and back again from the intermediate frequency position to the final audio at the receiving end produces a corresponding change in the frequency of the audio signal, cycle for cycle. Likewise, changes in the relative frequencies of the oscillators driving the modulators which perform the high-frequency translations both upward and downward cause a corresponding frequency difference between the audio input, and the audio output of the channel. To the ear, these changes are imperceptible unless they exceed about 20 cycles. If carrier system bands are connected together end on end in tandem, the frequency stability of all translating devices must be such that the over-all frequency drifts do not exceed the allowable tolerance. If certain bands are used for the transmission of dialing tones, or more particularly, if they are used for telegraphy, frequency changes between the two terminals must be held even closer. High-stability inductance-capacitance oscillators are used for all frequencies below 50 kc; above 50 kc the oscillators are crystal controlled. Over-all characteristics of all channels are such that frequency changes from input audio to output audio do not exceed about 10 cycles over long periods of time.

Since the intermediate frequency filters determine almost exclusively the attenuation characteristic within the voice band, this performance characteristic is strikingly uniform for all channels. Figure 7 shows that for a typical carrier system the over-all equivalent of the voice band does not deviate more than about 0.5 decibel from the 1,000-cycle reference point throughout the range from 200 cycles to 3,500 cycles. This characteristic is essentially the same whether measured at the 4-wire point or from the 2-wire side of the hybrid coil termination. A channel transmission characteristic measured through five systems connected in tandem end on end by patching at the 2-wire terminating points also is given in Figure 7. This shows less than −1 decibel and +2 decibels deviation from the 1,000-cycle equivalent.

Wave form distortion within a voice band of a carrier system may arise from a great variety of causes among which are nonlinearity of modulators, overloading of core materials in transformers and filters, and overloading of tubes both in individual channel amplifiers and common amplifiers. Good design keeps harmonics and cross-modulation products at such a low level that it is undetectable by the telephone user. It has recently become recognized that harmonics contribute but very little to wave form distortion unless the equipment design is extremely bad. Cross modulation between frequencies simultaneously transmitted within the band is far more likely to be offensive. Again, distortion resulting from this cause, while discernible to the ear is not easily measured with a speech current load. A quantitative evaluation is readily made, however, if the voice band load is a group of voice-frequency tone channels such as a telegraph carrier group. An indication of its magnitude in the type 42 system is given by a measurement of cross modulation between telegraph channels operated within a voice band. With 15 telegraph channels operating simultaneously within a band, a signal-noise ratio measurement on the 16th band shows a 35-decibel margin.

Common causes of residual noise (noise present on any one channel when all other channels are idle) are lack of adequate filtering in or proper stabilization of the power supplies, direct leakage or intermodulation of carrier or signaling frequencies, thermionic or microphonic noise in tubes, and noise in diodes of the modulators. Weighted residual noise power in a typical channel of the type 42 equipment is about 75 decibels below one milliwatt.

Interchannel crosstalk likewise can result from a number of sources: inadequate discrimination in the filters, cross-modulation in equipment elements common to all channels, or generally poor engineering design in the construction, shielding and wiring of the apparatus. In this system the long-time average interchannel crosstalk resulting from normal loads on the various channels does not exceed a weighted power level of about −67 decibels below 1 milliwatt.

Commercially available industrial vacuum tubes are used throughout. The modem oscillators have been so designed that their drift due to tube aging is inconsequential. Some drop in over-all system and in individual channel levels inevitably does result from undetected tube decay, even though reasonably good preventive maintenance tube inspection is realized. Over-all channel equivalents, however, can be maintained within very narrow limits by occasional adjustment of the channel regulator level controls. Pilot channel automatic level regulators, of course, will compensate in large measure for tube deterioration in the common equipment. Regulators hold the channel levels to within +0.5 and −1.0 decibels for attenuation changes in the transmission medium of +5 and −10 decibels with respect to nominal equivalent.

Adaptability

With a complete range of channel allocations from 12 kc to 208 kc available through the use of small compact interchangeable units, equipment assemblages are readily made up to provide all the groups commonly needed to coordinate with existing carrier systems of any type.

If the transmission circuit is to be an open-wire pair already in use for a conventional 6-band 2-wire 30-kc system, there is a choice of two methods of type 42 operation. Twelve channels may be added with allocations and directional separation as standardized for the widely-used type *J* carrier. The bands transmitted eastward then lie between 36 kc and 84 kc; and those transmitted west-

Figure 9. Automatic level regulator

Figure 10. Channel frequency allocations, types 42B and 42C systems

ward between 100 kc and 148 kc.

When more than one *J* system is applied to a lead, it is frequently very desirable to minimize crosstalk between systems by inverting and/or displacing the side band frequencies for the higher frequency direction of transmission, which is the east-west direction. This arrangement shifts the relative allocations of the principal energy-bearing components of the translated speech carrier and renders the remaining crosstalk interference unintelligible. This is commonly referred to as the "staggering advantage" of the frequency allocation.

With the type 42 system, inversion of the side bands for one direction of transmission is accomplished by selection of the upper rather than the lower side band in the second stage of modulation. Displacement of the side band is accomplished by correct choice of the carrier oscillator frequency for the second stage of modulation. These highly desirable alternate allocations for the higher frequency direction of transmission can then be accomplished without sacrificing any of the features which provide economies in the production of modem units.

Where line conditions permit noncoordinating 4-wire installations and where 24 or more 2-way channels are needed there may be economic advantages to a 4-wrie method of operation with 24 or more channels operating eastward on one pair and the same allocations used for westward transmission on another pair. With the same carrier line frequencies for each channel used for opposite directions of transmission, coupling between the two line pairs results only in "sidetone" interference but not in interchannel crosstalk.

On cable circuits where effectively isolated transmission paths are available, two 12-channel groups may readily be operated, the first using the allocations from 12 kc to 60 kc, and the second those between 72 and 120 kc. With selected cable pairs, several systems may be installed on a cable.

For radio working, any desired grouping of channels is readily assembled. If the linearity of the radio system permits, up to 48 channels would be possible on a single link. More often than not, however, particularly if the radio system involves repeater stations, marked advantage is had by keeping the channels within a single octave. This situation arises from the proclivity of presently available radio equipment to produce intermodulation distortion. Depending upon the particular design of the radio equipment, the advantage in signal-noise ratio of confining the used "audio" spectrum to one octave may vary from 6 decibels to as much as 16 decibels. If this restriction is imposed, channel allocations between 00 and 108 kc, 12 channels, or between 100 and 196 kc, 24 channels, are commonly chosen, depending upon the load capacity and modulation frequency limitations of the radio equipment.

Twelve channel groups of whatever allocation needed are easily assembled. System assemblies of 12 channel groups are facilitated, and repeater regulation and flat and "twist" equalization problems are simplified by handling each group more or less independently from terminal to terminal. This is accomplished by interconnecting the carrier frequency lines of the groups through group filters and hybrid transformers as shown in Figure 8. At repeaters and at terminals, each group is amplified and equalized separately. If automatic gain regulation is used, a pilot control frequency is assigned to each group.

The wholly electronic level regulator is shown by Figure 9. Briefly, the pilot frequency is separated out, amplified, and mixed with a locally generated frequency 4 kc removed. A second simple filter selects the difference frequency resulting. This is amplified and rectified. The direct current thus obtained is made to adjust the transhybrid loss of a hybrid transformer type of bridge, one arm of which is a current sensitive resistor.

Type 42 equipment is engineered on the building-block basis, now virtually a standard for carrier systems. Basic terminal assemblies provide only moderate

transmitting and receiving gains which permit the installation of low-cost systems for short circuits. Optional booster amplifiers can be installed when needed to convert the equipment to long-haul use. Inexpensive pilot regulator equipment suitable for short-haul systems or systems installed on leads which are not exposed to weather extremes can be replaced where required by more complex regulators.

The over-all design permits application of type 42 equipment to a wide range of open wire line, cable or radio link applications, yet component assemblies are standardized to make possible volume of manufacture and the resultant economies. A high degree of stability and ease of maintenance has been accomplished by careful attention to detail.

An Improved Transmitted Carrier System for Telephone Lines of Short or Medium Length

G. H. BRODIE
NONMEMBER AIEE

Synopsis: This paper describes a stackable 1-, 2-, or 3-channel short-to-medium haul telephone carrier system, which has been developed primarily to meet the needs of the independent telephone field. Features of this type number 5 carrier system are transmitted carrier frequencies in harmonic relationship, ringdown signaling by carrier interruption, dial signaling by carrier frequency shift, excellent transmission capabilities, particularly in the second and third channels, and simple installation, testing, and maintenance procedure. Partial suppression of the transmitted carrier frequencies is available, for the occasional application in which the normally higher carrier level on the line might prove objectionable. Through particular attention to the engineering design, the significant objections to transmitted carrier have been overcome, while its greater convenience to the user has been employed to good advantage. The feasibility and desirability of this system have been amply proved by hundreds of successful installations, some of which are on difficult lines where other carrier systems previously failed.

TRANSMISSION of the carrier frequency on telephone lines is as old as carrier telephony itself, but, in the first successful use of carrier circuits on multiple long lines applications, this practice fell into disfavor for the reasons set forth by Colpitts and Blackwell[1] in 1921. Several of the important advantages associated with transmitted carrier were recognized at that time but they were held to be outweighed by its disadvantages. Considering the nature of typical long lines applications and the state of the art in those early days, suppression of the carrier appears to have been the only logical choice. But the use of telephone carrier circuits no longer is confined to long lines and the state of the art had advanced a great deal.

There are 6,106 independent telephone companies in the United States and possessions[2] which are operating, for the most part, over lines of short-to-medium electrical lengths. Bell Telephone companies serving rural areas, many railroads, oil companies, and other organizations own and operate additional lines of similar characteristics. Since World War II the use of carrier circuits on such lines has become widespread and is increasing rapidly. Here the requirements and operating conditions usually differ materially from those found on long lines applications. For these reasons, it does not follow that the type of carrier system most suitable for one field must also be best for the other.

Contemporaneously with the increased use of carrier systems on the shorter independent lines, several makes of equipment have been presented to fill the need in this field.[3–8] These differ from each other in details, but all carry over into this newer field the old "long lines-suppressed carrier" approach.

Where technical personnel is available to make the necessary measurements and adjustments, suppressed carrier systems generally are satisfactory. They do, however, impose unnecessary hardship on the small company where suitably trained technicians are not always available. Furthermore, the desirable characteristics of suppressed carrier systems are of less importance in the independent field than in multiple long lines applications. Conversely, the increased simplicity of adjustment and maintenance possible with a transmitted carrier system becomes of relatively greater importance.

It was our conviction that a transmitted carrier system, if a suitable one could be developed, would be of great advantage to most independent operators. This conviction resulted in the production, early in 1947, of a single-channel carrier system operating on the transmitted carrier principle. The first model was readily accepted in the independent field and almost immediately proved its worth. From this beginning the stackable 1-, 2-, or 3-channel type Number 5 carrier system, as described in this paper, came into being.

It is interesting to note that, while this development was in process, an increased interest also was shown in transmitted carrier systems in Australia.[9] As the advantages possible with equipment of this type become more generally appreciated, it seems likely that its use in the independent field will become more general.

Description and General Considerations

Figure 1 shows the general appearance and arrangement of the various panel-mounted units making up a complete 3-channel terminal for the type Number 5 carrier system. The arrangement shown is for ringdown signaling over the first channel and dial signaling over the second and third, with power obtained from two Number 105 power supplies. A single heavier duty power supply can be used to save rack space, and signaling units can be of the dial or the ringdown type on any of the channels. Standard 19-inch rack space required for a single-channel terminal is $22^3/_4$ inches. For two channels

Paper 50-241 recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 24, 1950; made available for printing September 1, 1950.

G. H. Brodie is Chief Research Engineer with the Kellogg Switchboard and Supply Company, Chicago, Ill.

The author is indebted to the engineers who developed and tested the Number 5 carrier system, particularly C. E. Wood, O. Blyholder, B. E. Swanson, and O. S. Ostberg.

Figure 1. General appearance of a 3-channel carrier system terminal

Figure 3. Block diagram of 3-channel terminal

this becomes 35 inches; and for three channels with one power supply, $47^1/_4$ inches. With two power supplies the figure is increased by 7 inches.

Considering the panel-mounted units from top to bottom, the first is a conventional power supply delivering 200 volts of direct current and 6.3 volts of alternating current. The second is the line unit consisting of high and low pass line filters, a carrier frequency repeating coil, and a simple balancing network to be inserted in the other pair of a phantom group when no carrier is installed thereon. The third unit is the first channel carrier terminal and the fourth is its associated ringdown signaling unit. Number five is the second channel carrier terminal and six is its associated dial signaling unit. Numbers seven and eight are the third channel units corresponding to five and six respectively, while Number nine is the second power supply.

The frequency allocations for this carrier system and, for comparison, the Association of American Railroad's carrier frequency agreement,[18] are shown by Figure 2. It may be noted that the carrier frequencies are in such harmonic relationship that they can generate no beat frequency falling in either the audio or in one of the carrier bands. Thus one of the disadvantages sometimes associated with transmitted carriers is circumvented.

The over-all layout and sequence of operations in this system are illustrated in block diagram form by Figure 3.

While the carrier terminal panels for each of the three channels are similar in size and general appearance, the first channel uses no power amplifier tube and transmits at a maximum level of 10 decibels above one milliwatt. The second and third channels employ power amplification and transmit at a maximum level of 20 decibels above one milliwatt. The available transmitting and receiving gain is approximately 23 decibels for the first channel and 35 decibels for the second and third channels. With this arrangement, performance measured in miles of typical line is approximately equal for the first and second channels, with the third channel dropping from $12^1/_2$ to 30 per cent.

Since the elimination of objectionable intermodulation products is a serious problem, particularly in a multichannel carrier system employing transmitted carrier at relatively high levels, very careful consideration has been given to the design of the filters and other circuit elements. The inductance of certain coils in the band-pass and other carrier frequency filters must remain constant from the lowest to the highest signal level. This means that large powered metal or oxide cores of low permeability, or air cores, are required.

In the case of the carrier frequency repeating coils, a Mu metal core is used which provides a high initial permeability and also holds its permeability reasonably constant throughout the range of the magnetizing force encountered. Thus,

Figure 2. Type Number 5 and American Association of Railroads frequency assignments

Figure 4 (left). Frequency response of filter for east-west band of second channel

Figure 5 (above). Voice frequency response through a 25-decibel line

by using an adequate cross section, thin laminations, and a large number of turns, intermodulation products from this source are kept very low.

Excellent frequency stability over a wide temperature range is attained through the use of stabilized toroidal inductors and a special type of ceramic capacitor, with air dielectric variable capacitors for making the final adjustments.

Band filter requirements are fairly severe in a carrier system of this type, since the other high level carriers, as well as their associated sidebands, must be excluded from a given channel. This applies most forcefully with respect to the carriers transmitted in the opposite direction. Very high attenuation outside of the pass band, with rejection notches where they are most helpful, keep interchannel cross talk well below the generally accepted one millivolt level. The frequency response of a typical bandpass filter is shown by Figure 4.

When the carrier is transmitted at full strength, a small amount of low-frequency signal from the rejected sideband unavoidably is included. Suitable equalization is built into the receiving circuits to correct for the increased low-frequency audio signal which otherwise would result. Actually, the over-all response is uniform within 3 to 4 decibels from 250 to 2,750 cycles approximately (Figure 5).

Another disadvantage commonly associated with transmitted carrier systems is that one (or more) of the carrier frequencies present on the line, at levels several decibels higher than that of the sidebands, is likely to be picked up by other makes of carrier systems on the same pole line and be demodulated in the receiving terminal. There it would appear as a steady audio tone. It has been our experience that such conditions are only seldom encountered in the independent telephone field. An inexpensive provision has been made, however, to partially suppress the carrier frequencies on the type Number 5 system when it is necessary or desirable to do so. These frequencies then appear on the line at levels no higher than the sidebands and are selectively amplified to the desired extent in the receiving terminals.

In the early days of telephone carrier practice the vacuum tubes then available limited the power which could be handled conveniently to rather low levels. Today it is entirely practicable to handle powers in excess of one watt in the final amplifier, so the former objection that transmitted carrier would overload the amplifier tubes is no longer very significant.

Principles of Operation

Except as the processes are modified by the characteristic features mentioned elsewhere in this paper, voice frequency signals are transmitted and received in the conventional manner.

The extreme simplicity of the ringdown method of signaling is easily understood from a short study of Figure 6. Ringing voltage, when applied across the carrier circuit drop, interrupts the transmitted carrier. At the distant terminal the interruption of the carrier places ringing voltage from a local source across the carrier circuit drop, causing operation of a switchboard signal, or a telephone ringer, in the normal manner.

The dial signaling unit, as shown schematically by Figure 7, provides means for accepting d-c pulses at the local carrier terminal and for delivering duplicate pulses to a suitable circuit associated with the distant terminal. Full supervision is available at all times as will be shown. The required signaling functions are performed by causing the carrier frequency to shift slightly each time battery voltage is applied to or removed from the "M" lead. The amount of shift is not enough to interfere with voice frequency transmission, but is enough to cause the discriminator and biased triode amplifier at the receiving end to operate a relay. The discriminator and signaling relay faithfully reproduce the dial pulses just as they come into the carrier system.

Considering a call from a toll operator to an automatic telephone office, the operation of the carrier shift principle is as follows. With the carrier channel idle, each carrier stands shifted to its off-normal frequency. When the operator at the east terminal plugs into the drop circuit, battery voltage is placed on the "M" lead. This operates the dialing relay and shifts the westbound carrier back to normal frequency. The change in frequency operates the signal relay con-

Figure 6. Circuit schematic of ring-down signal unit

Figure 7. Circuit schematic of dial signal unit

trolled by the discriminator at the west terminal which puts ground on the "E" lead. This permits battery current to flow in the trunk entering the automatic switching equipment in the west central office. The trunk is seized and dial tone is passed back into the west terminal carrier circuit drop to indicate to the operator that the switching mechanism is ready to receive dial pulses.

The west-to-east carrier is still on its off-normal frequency but the circuit is capable of perfect audio transmission and reception. The east operator hears the dial tone and proceeds to dial the required digits. Each pulse temporarily shifts the frequency of the east-west carrier to off-normal. The normal frequency corresponds to the makes and the off-normal frequency to the breaks at the calling dial or sender. The signaling relay at the west terminal reproduces these dial pulses and passes them along on the "E" lead to the west central office. After the dialing operations are completed the east-west carrier remains on normal frequency. The mechanism in the west office connects the incoming trunk to the called line and revertive ringing tone (or busy signal) comes back to the caller over the west-east band of the channel, with this carrier frequency still off-normal.

When the called party answers, battery voltage is placed on the "M" lead of the west terminal, causing the west-east carrier to shift to normal frequency. This shift places ground on the "E" lead at the east terminal, causing the operator's supervisory lamp to go dark. The two parties then converse with each carrier on its normal frequency. When the called party hangs up, battery voltage is removed from the "M" lead at the west terminal, allowing the west-east carrier to shift to its off-normal frequency. This shift takes ground off the "E" lead at the east terminal, allowing the operator's supervisory light to glow. The operator then withdraws the cord, removing battery from the "M" lead at the east terminal, and restoring the east-west carrier to off-normal frequency. This last frequency shift takes ground from the "E" lead at the west terminal, which in turn releases the circuits in the automatic switchboard. The carrier channel is then in its standby position, ready for another call.

Advantages

This type of transmitted carrier system enjoys the following advantages, as compared with suppressed carrier equipment:

1. Neither synchronization of local and distant oscillators nor critical carrier leak adjustments are required.
2. The carrier frequency signal can be traced through the entire system and measured easily when the channel is either in use or idle.
3. Ringdown signaling can be accomplished in a simple and inexpensive manner.
4. Receiving oscillators are not required.
5. Voice frequency shift is eliminated.
6. Neither additional pilot frequencies nor extra bands for dialing or signaling are required.
7. The basis for an automatic circuit failure alarm is provided.
8. A simple method of modulation, without use of transformers is made possible.
9. Installation, testing, and maintenance are greatly simplified.

Some 300 type Number 5 carrier systems, distributed over nearly all sections of this country, now are operating satisfactorily with a minimum of maintenance. Although some of these installations are on difficult lines where, previously, other carrier systems failed, very few troubles of any sort have been encountered. This indicates that a transmitted carrier system, designed and constructed as described, is particularly suitable for use on lines such as those most frequently employed in independent telephone field.

No Discussion

A Medium-Haul Carrier Telephone System

HOWARD H. SMITH
NONMEMBER AIEE

CARRIER TELEPHONE equipment has been in use for about 30 years, and its place in providing economical long-range circuits has become well understood and widely accepted. However, the recent amazing growth in demand for more communication channels on the part of both private communication operators and common carrier telephone companies has been accompanied by a change in requirements which has begun to make many present carrier systems obsolescent. We now find carrier telephone channels serving to multiplex broad-band radio links as well as providing circuit relief in relatively short trunk groups in the local or medium-range toll wire plant. The great rise in toll and long distance dialing requirements has forced reconsideration of the provisions for signaling. Space is becoming a serious problem in many offices. As carrier is adopted by more of the smaller companies because of its attractive low initial cost, new problems involving maintenance by personnel with little electronic background must be faced.

Telephone circuits are now sometimes required to handle one or more voice-frequency channels in place of, or in addition to the speech, which may be used for telegraphy, telemetering, supervisory control, pilot relaying and many other purposes limited only by the ingenuity of the users. As part of radio systems, they help provide remote control and alarm features. It is the purpose of this paper to analyze these functions and to describe a new carrier telephone system which has been designed specifically to meet a majority of these requirements.

Paper 50-242, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted August 2, 1950; made available for printing September 11, 1950.

HOWARD H. SMITH is with the Federal Telephone and Radio Corporation, Clifton, N. J.

General

When the earlier carrier telephone systems were introduced, the need was principally for relatively long-haul channels, with simple signaling on a 2-way ringdown basis between operators. Some systems employed an audible-frequency signal somewhere in the speech band, with various provisions to hinder speech sounds from causing a false signal, others made use of methods in which the entire speech channel was made inoperative during ringing intervals. The former arrangement was very difficult to adapt for dialing, while the latter made it impossible to use speech-plus or simultaneous speech and voice-frequency or control systems. To eliminate these limitations in existing systems is generally costly. With these and other similar factors in mind, it is clear that the communications engineer must avoid investment in obsolescent types of equipment by anticipating the trends in signaling, as well as the requirements for speech transmission.

Long-, Short- and Medium-Haul Systems

Long-haul systems are generally understood to be those capable of placing carrier currents on open-wire lines at levels up to +15 to +18 dbm (decibels referred to 1 milliwatt in 600 ohms) and capable of receiving signals down to about −18 dbm, with provision for extending the range more or less indefinitely by use of carrier repeaters. Automatic level regulation is a practical necessity for such systems. Attempts were made to answer the need for relatively short circuits by what were termed short-haul carrier systems, of one or more channels. These generally had only sufficient amplification to operate over lines with carrier-frequency attenuations up to 10 to 18 decibels maximum. While short-haul systems operated successfully within these limitations, it was found that they could not be used on a considerable number of short wire lines because of entrance cable losses.

Much wire plant was installed before inexpensive carrier equipment became available, and it often turns out that one or two miles of 19, 22, or even in some cases, 24-gauge (American wire gauge) nonloaded cable pairs must be included in the circuit unless expensive alterations are to be made. The losses introduced at carrier frequencies by such pieces of cable often exceeded the total available gain of a short-haul carrier system, although the total geographical length of the circuit might be 10 or 15 miles, or less. It thus became apparent that for such service, a carrier system with gains and levels approaching those of long-haul systems was required, but that some long-haul features such as line-slope equalization, and automatic level regulation could be omitted. Such systems are designated as medium-haul systems. Depending on conditions, they may be from 5 to 200 miles in actual length.

Medium-Haul Transmission Requirements

The medium-haul category includes most of the intrastate toll and trunk telephone circuits up to 200 miles, as well as longer circuits of the railroads, pipelines, and power utilities. Many are operated at net losses as low as 2 decibels, the average being 4 to 6 decibels. A reasonably flat audio bandwidth between 300 and 2,700 cycles per second is acceptable, while the upper limit may be lowered to about 2,200 cycles per second in many interoffice trunks and terminal toll circuits.

Choice of Carrier Frequencies and Levels

Where carrier channels are to be added to lines already equipped with some carrier systems, it is desirable to observe proper co-ordination of frequencies and power levels of the various systems. Any new system should be capable of transmitting levels of at least +12 dbm, and receiving levels as low as −15 dbm. The side bands transmitted should lie in the frequency bands conventionally accepted for east-to-west and west-to-east transmissions.

Carrier Frequency Stability

Since efficient use of the available carrier-frequency spectrum practically dictates use of single side band, suppressed-carrier transmission, the question of how close the frequency of the demodulator oscillator must be kept to that of the oscillator at the transmitting terminal, is imposed when the telephone channel is used for one or more subcarrier channels of amplitude-modulated or frequency-shift telegraphy or telemetering. Under these conditions, the maximum tolerable departure from synchronization is of the order of 10 cycles per second. Otherwise, however, it can be demonstrated that a deviation of 20 cycles alone will cause no noticeable distortion in speech. But if it is combined with excessive carrier leak, low line losses, and poor hybrid balances, very weird sounds may be heard, and the circuit may be made quite unacceptable. A beating effect is sometimes very prominent, and since the other effects tend to disappear when zero beat is attained, a natural reaction is to concentrate upon maintaining absolute carrier synchronization. However, if proper steps are taken to reduce carrier leak by improving modulator balance, or to correct the poor hybrid balance, or to align system levels properly, the synchronization problem promptly vanishes. Therefore we may conclude that if the carrier oscillators are themselves constant to within 2 or 3 cycles per second, further synchronization is not ordinarily justified economically. This figure thus represents a rational design requirement for the stability of a carrier oscillator for a carrier telephone system.

Signaling Requirements

Since practically all telephone circuits are used intermittently, it is necessary to provide for signaling in both directions between opposite ends. Manual and automatic switchboards use d-c signals and impulses, and a-c signals with frequencies below 100 cycles per second, for such purposes as dialing, supervision, and ringing. Obviously these signals cannot be sent as such over a telephone channel which passes only frequencies between 300 and 2,700 cycles, with power of the order of one milliwatt. Equivalent results must be obtained by transmitting some other kind of signal either in the carrier-frequency band used by the speech, or adjacent to it, and establishing a relation between it and the a-c or d-c signal paths at the terminals. Such a signaling system must:

1. Provide a separate signaling path in each direction.
2. Create no interference with the normal functioning of the speech channel.
3. It must be immune from false operation by speech currents.
4. Should be capable of transmitting all types of signaling, such as 20-cycle ringing, telephone dialing and supervision, railway selector impulses at a $3\frac{1}{2}$-cycle rate, and the like.

Each 1-way signaling channel is similar to a 1-way telegraph channel, and will usually require a transmitting relay and a receiving relay. The transmitting relay may be required to operate on a-c ringing current for ringdown service, or on d-c dial or supervisory or other control signals, depending on its application, so that it is desirable to be able to change the relay type readily. The receiving relay may be required to apply ringing current to the talking conductors toward the switchboard drop, or to repeat various d-c impulses over separate conductors. It is therefore preferable that the signaling circuits be flexible so that by a minimum of adjustment and strapping, a terminal may be set up for any of the common ringdown or dialing circuit arrangements. In dial operation signaling circuits are required to perform perfectly under a wide variety of circuit conditions where the impulses transmitted may be badly distorted at their source. Under these circumstances, it is imperative that the signaling circuit contain means for adjusting the dial pulse ratio, since the additional relays in the circuits between the carrier and the exchanges may produce additional distortion.

In ringdown operation, difficulty is sometimes experienced due to transient discharges from capacitance in switchboard circuits causing a false ring to be transmitted in the opposite direction at the end of a ringing signal. It is highly desirable for the carrier equipment to be able to suppress such false operation.

Sometimes it may be required that a carrier telephone channel be connected permanently to a common battery telephone subscriber set, at a location where telephone office battery and ringing current are not available. For such cases, it is desirable to be able to supply direct current from the carrier set for talking battery, through the windings of the signaling transmitting relay. The latter thus serves as a line relay, and can repeat hook-switch indications and dialing impulses to the central office. The ringers of most telephone sets can be adjusted to ring fairly well on 50- or 60-cycle alternating current, or ringers of harmonic ringing types can be substituted, so that provision of a suitable winding on the carrier power-supply transformer will take care of the ringing requirements in most cases. The circuit of the receiving relay should be adaptable by some means to permit setting up the ringing circuit.

Carrier Channel Line Circuit Arrangements

The most flexible arrangement of carrier channels is that which provides stackable channels connected to the line or radio system through common line filters, separate from the channel equipment. In such an arrangement, it is convenient to mount a pair of line filters together, which will serve an open-wire phantom group, or a radio-link transmitter and receiver. In the latter case, addition of a hybrid coil circuit facilitates derivation of a 2-wire audio channel over the radio link. The transmitting filters for all channels are connected in parallel, as are the receiving filters, and connected to their respective transmitting and receiving line filters for a radio link. For 2-wire physical lines, the transmitting and receiving filters are all connected together and to the line filter.

In wire line applications, especially in 1- or 2-channel systems, some compactness may be gained by including the line filter on the terminal panel for the first or lowest frequency channel.

Separate line filters are required to provide transfer sets to by-pass obstacles and for balancing line filters for line-balancing networks of 2-wire telephone repeaters. In a stackable system, a line filter should be provided with a cutoff frequency just below each channel, to permit superposition of higher frequency channels over lower frequency systems of different type, and to permit separating channels at various points where one or more are dropped, or where they must diverge.

Carrier Channel Drop Circuit Arrangements

It is desirable to be able to terminate the voice-frequency side of a carrier channel on either a 2-wire or a 4-wire basis. For use when the channel is connected to a 2-wire switchboard, a compromise network should be provided capable of giving a moderate balance against the various types of terminations which may be connected. Provision should be made to permit substitution of an external balancing network when a more precise balance is required, as when the carrier circuit is extended by a permanent connection to a line. When it is required to operate the channel on a 4-wire drop basis, as for back-to-back connection to another channel, or for other reasons, it is desirable to be able to convert the hybrid coil circuit into separate input and output circuits operable with 600-ohm circuits, either balanced or unbalanced with respect to ground.

Requirements for drop transmitting and receiving levels usually are different for 2-wire and 4-wire operation. While the level transmitted from 2-wire drop into the hybrid is normally considered to be at a test power level of 0 dbm (1 milliwatt), the modulator input on a 4-wire basis is commonly desired to be at a −13 dbm level. Likewise, the output from the hybrid into the 2-wire drop may be at a −2 dbm level, down to −8 dbm or lower, but it is commonly required that the demodulator branch output be +4 dbm on a 4-wire basis. Suitable pads or level controls should be provided to permit meeting the required 2-wire and 4-wire levels, preferably without having to do soldering or substitution of removable elements.

Installation and Maintenance Requirements

In an extensive toll plant employing many telephone repeaters and carrier systems, it may be necessary to line up levels and net losses of circuits to within a few tenths of a decibel, and to maintain them within such limits. For this purpose it is practicable to install relatively expensive oscillators and transmission measuring equipment, and to train people to use it properly. In such a situation, controls may be adjusted and readjusted according to meter readings, and there is little need to mark or record the physical settings.

However, many users are purchasing carrier for the first time, and the carrier may be the first electronic equipment in the plant, with possibilities of growth limited. In such cases it is desirable that the installation and maintenance of a medium-haul carrier system should not require highly trained personnel and elaborate measuring equipment. A medium-haul carrier telephone system should be designed so that a workable circuit adjustment could be obtained with approximately the following test equipment:

1. A-c–d-c volt-ohmmeter with decibel scale reading down to about −15 dbm.
2. Oscillator giving 1,000-cycle test tone a 0-dbm level, with 600-o hm-output impedance.
3. Telephone dial in good adjustment, when dialing is involved.

The oscillator and decibel meter may be used to adjust the net loss of the talking circuit, on an audio-to-audio basis, relying on the factory-set carrier transmitting level. The performance of the dialing channel in terms of dial pulse ratio may be measured with the dial and ohmmeter, the latter serving as a pulse ratio meter. Often such work must be done by a single technical man, with a relatively unskilled helper. If all line-up and routine maintenance adjustments may be made by means of controls having knobs and closely graduated dials or scales, the assistant may be directed to make adjustments and report settings by telephone, thereby greatly expediting the work. Provision of clearly marked test points, and places where the circuit may be cut for testing, by jacks or removable test links, is of additional assistance.

Compactness

Where only one or two carrier terminals are installed in an office, physical size is relatively unimportant. However, when dozens of terminals must be given space, a floor space problem is frequently encountered. With the rising costs of building, and in some cases limitations of space available to extend the building, it becomes highly important to make carrier equipment as compact as may be consistent with convenient maintenance accessibility.

Description of Federal 9-H-2 Medium-Haul Carrier Telephone System

A 3-channel system was developed, capable of being installed one channel at a time, with the same equipment interchangeably used to provide a 6-channel system operating on a 4-wire basis over broad-band radio links of suitable characteristics. Thus the same voice-frequency and signaling features are available for wire and radio systems, so that the resulting circuits appear in terminating offices on exactly the same basis. While retaining the accessibility of parts for adjustment and maintenance, a relatively compact physical design was achieved, whereby each channel is completely contained on a single panel, from line filter to power supply, ready to plug in. Additional channels including their own power supplies, not requiring line filters, are stacked physically and electrically up to the maximum number.

Frequency Allocation

This system uses single-side band, carrier-suppressed transmission, with separate carrier frequencies for each direction of transmission. The signaling frequencies lie outside the utilized speech side bands, being 3.4 kc away from the carrier frequency on the same side as the speech band. It was arranged that the transmitted energy from the various channels would co-ordinate with a scheme of frequency allocation which is generally recognized, in which the long-haul systems use frequencies below about 17 kc for east-to-west (or north-to-south) transmission, and frequencies from about 17 kc up to about 30 kc for west-to-east (or south-to-north) transmission. This scheme also permits use of the band be-

Figure 1. Frequency allocation, 9-H-2 carrier telephone system.

Figure 2. Block diagram, 9-H-2 terminal

tween approximately 3 kc and 7 kc for west-to-east transmission, which is used for the return side of single-channel systems.

This frequency allocation is shown in Figure 1, along with the actual assignments selected. Channel 1 uses the bands for single-channel systems. Channel 2 straddles the 17-kc break of the 3-channel allocation, while channel 3 uses the top part of the 3-channel allocation for west-to-east transmission, and a return band lying above 30 kc which is outside the normally used 3-channel allocation.

For the record, the frequencies of carrier, transmitted side band and signaling channels are as shown in Table I.

The spacing of the channels is increased slightly and progressively at the higher frequencies partly as a matter of filter economy, and partly to fit into the standard frequency-band allocation.

Table I

Channel	Terminal	Carrier Frequency, Kc	Transmitted Side Band, Kc	Transmitted Signal Frequency, Kc
1	West	7.0	4.3– 6.7*	3.6
1	East	9.0	9.3–11.7**	12.4
2	East	17.0	14.3–16.7*	13.6
2	West	19.5	19.8–22.2**	22.9
3	West	26.0	26.3–28.7**	29.4
3	East	35.0	32.3–34.7*	31.6

*Lower side band.

**Upper side band.

Analysis of Circuits

Functionally the circuits of a complete channel terminal may be broken into seven parts, which are as follows:

1. Speech transmitter circuit.
2. Speech receiver circuit.
3. Signaling transmitter circuit.
4. Signaling receiver circuit.
5. Voice-frequency terminating circuits.
6. Carrier-frequency terminating circuits.
7. Power supply circuits.

These will next be discussed with the aid of the block diagram, Figure 2.

Speech Transmitter Circuit

This consists of the upper main branch of the circuit. Speech arriving from the left through the hybrid coil circuit passes first through a 2,700-cycle low-pass filter to remove speech currents above that frequency. An equalizer is inserted next to flatten the channel frequency response. Entering the modulator circuit, the speech currents are transformed by the alternate blocking and unblocking of germanium diodes at carrier frequency into upper and lower side bands, only one of which is to be utilized. In this type of modulator, the carrier frequency is suppressed, appearing in the output circuit only due to unbalances in the modulator. An adjustable resistor is provided to facilitate the adjustment of carrier leak to at least 20 decibels below the test power level. The modulator also suppresses the original speech frequencies.

The modulator band-pass filter selects the upper or lower side band as required by the frequency allocation, permitting it to pass through a 3-decibel matching pad to the transmitting amplifier input transformer. At this point the transmitting signaling current is introduced, as described later. The transmitting level-adjustment control is thus common to the speech side band and the signaling channel, permitting their simultaneous adjustment to meet transmitting level requirements without disturbing the ratio between them. The 2-stage transmitting amplifier is followed by a filter which has two purposes. One is to reduce further undesired frequencies from the channel output. The other purpose is to prevent the output resistance of the amplifier from being shunted across the filters of the other channels, by providing impedance

Figure 3. Typical channel loss-frequency characteristic, 9-H-2 carrier telephone system

matching only in its transmitted band. The output of the transmitting filter is applied to the high-pass part of the line filter in parallel with the other channels.

Speech Receiver Circuit

Carrier-frequency side band currents arriving from the distant speech transmitter circuit from the right are separated from those of other channels by the receiving band filter. This is followed by a carrier receive-level attenuator control which is adjusted to bring signals to a nominal level before application to the demodulator. The demodulator is substantially identical to the modulator, and its output consists of the unwanted high carrier frequencies resulting from interaction between the side band and the carrier, and the desired low frequencies which reproduce the original speech. Both groups are amplified by a fixed gain amplifier, and applied to a 2,700-cycle low-pass filter which eliminates the undesired frequencies from the output. Following the equalizer of the receiving channel is a second level control, affecting only the speech receive level. The received signaling current is also demodulated, producing a 3,400-cycle current which is picked off by a filter, described later. A typical over-all channel loss versus frequency characteristic is given in Figure 3.

Figure 4. Pulse ratio control circuit operation, no correction of pulse length

Figure 5. Pulse ratio control circuit operation, adjustment to lengthen pulses

Figure 6. Pulse ratio control circuit operation, adjustment to shorten pulses

Signaling Transmitter Circuit

The signaling oscillator is in operation continuously, but its output is short-circuited by contacts of a relay as a means of keying it. The oscillator generates a signal 3.4 kc away from the carrier, on the same side as the speech side band to be used. It is thus equivalent to use of a 3,400-cycle signaling tone originating on the speech side of the modulator. However, by not passing the signal through the modulator, certain interaction products are thereby avoided. The level of the signaling current relative to the speech side band may be adjusted in steps which are usually preset at the factory. The sending or transmitting relay is either an a-c relay for operation on nominal 20-cycle or other low-frequency ringing current, or a 2-winding d-c relay for operation as a line relay or as controlled over a signaling or dialing lead by associated equipment. Relays are conventional telephone type, mounted on plug-in bases for ease of interchange or for convenience of adjustment. The circuit may be wired to permit transmission of the signaling tone when the transmitting relay is operated, or when it is idle, by a strapping change.

Although the signal lies outside of the speech side band, all things being equal, it is desirable to have the signal cut off during the time the circuit is in use for speech. For ringdown operation, therefore, the relay normally short circuits the tone, whereas in dialing operation, it is usually arranged to leave the tone on the line until the circuit is seized for a call. Dial impulses at speeds up to about 14 per second may be transmitted.

Signaling Receiver Circuit

The 3,400-cycle signals which appear in the output of the receiving amplifier are selected by a 3,400-cycle band-pass filter and applied to the input of the signal receiving circuit through a gain control. The signal receiving circuit consists of vacuum tube circuits which both amplify and limit the signal, the output being delivered by means of a telephone-type receiving relay in the anode circuit of the last tube. The operation of the circuit is such that in the absence of received tone, the relay is operated. Received tone applies negative bias to the last grid, causing the relay to release. A feature of considerable utility in dialing service is a pulse-ratio control circuit. This may be adjusted so as to vary the length of the output pulses relative to those delivered by the associated circuits at the distant transmitting office, which is of value in dialing operation as a means of correcting a certain amount of distortion which might otherwise exist due to repetition through a number of pulsing relays in tandem. Figures 4, 5, and 6 indicate the forms of voltage impulses applied to the last grid, and the resulting relay output impulses for no pulse ratio correction, for lengthening and for shortening the impulse, respectively. Figure 7 is a curve representing the effect of changes in the level of the received signal on the output pulse ratio, for a given setting of the control.

The pulse-ratio control circuit also is useful in some ringdown applications in which a kick-back occurs at the end of a received ringing signal, causing a false signal to be transmitted back to the other terminal. This transient disturbance is frequently caused by capacitance in the switchboard circuits. In some cases, circuit engineers have added slow-releasing relay circuits to such switchboard circuits to delay the restoration of the circuit to normal until these charges have had time to leak off. These measures are rendered unnecessary if the false ringing signal can

Figure 7. Change in pulse ratio versus received signal level

Figure 8. Two-coil hybrid circuit for 2-wire or 4-wire operation

be prevented from reaching the switchboard. By increasing the time-constant of the pulse-ratio control circuit by a factor of 20, sufficient delay may be introduced to keep a momentary false ringing signal from operating the receiving relay. The length of delay is adjustable by use of the same control used for dial pulse-ratio adjustment.

The receiving relay is a single-winding d-c telephone relay, of a type adaptable for either connecting ringing current to the switchboard or other drop in ring-down operation, or for repeating dialing or other d-c signals. It is mounted on a plug-in base.

Voice-Frequency Terminating Circuits

For most applications, it is necessary to connect the transmitting and receiving speech channels to an ordinary 2-wire telephone circuit. This is done by use of a conventional 2-coil hybrid or 4-wire terminating circuit, equipped with a compromise network for operation under average switchboard or subscriber set conditions. The 2-coil hybrid circuit used has several advantages over the frequently-used single-coil circuit, which utilizes line and network windings which have common junction points. One advantage is that the line, network, modulator, and demodulator circuits are all insulated from one another. A second is that the circuits may all be any impedance desired, in this case, 600 ohms. A third advantage is that the circuits of the two coils may be separated, converting them into independent input and output transformers. When used in this way, an additional section of winding is provided to give 600-ohm impedances toward the drop. Figure 8 shows this arrangement. Provision also is made to disconnect the compromise network in case it is desired to obtain a more precise balance by use of a separate external network, as when the drop side of the carrier terminal is permanently connected to a 2-wire cable or open-wire circuit of more than nominal length. Figures 9 and 10 indicate how this 2-coil hybrid circuit functions with speech currents from and to the drop.

The signal transmitting and receiving relays may be connected to the hybrid circuit and the associated external equipment in a number of different ways, by means of wiring between terminals on the main panel terminal strip. The separation filters required for speech-plus-duplex telegraph or tone signaling systems may be introduced on either the 2-wire or 4-wire side of the hybrid circuit, as required by the application. The filters for 4-wire application are inserted between the terminals marked *S-P*.

A 9-decibel pad is provided adjacent to the hybrid winding leading to the modulator circuit, controlled by a U-link which may be moved between its IN and OUT positions as desired. In the 4-wire drop arrangement of the hybrid coil circuit, this pad may be cut out, so that speech signals corresponding to −13 dbm test power level may be applied to the 4-wire sending circuit from the drop. In the 2-wire drop arrangement, this pad is cut in, so that the modulator will operate at its proper levels with speech signals corresponding to 0-dbm test power level received from the 2-wire drop.

Carrier Frequency Terminating Circuits

In operation over 2-wire line facilities, the transmitting and receiving filters of all channels are connected in parallel to the high-pass portion of the line filter. The latter passes all frequencies above about 3 kc, including the 3.6-kc signal of the lower half of the first channel. Only one line filter is required in this case for all three channels. This filter is commonly provided on the panel of the first channel in wire applications, as a measure of compactness, although for maximum flexibility it is sometimes supplied on a separate panel, with appropriate test U-links. The high-pass line filter and all of the channel filters are designed to have one side grounded for compactness and economy of manufacture. The low-pass line filter, however, is required to operate in a balanced circuit, and is normally inserted between the d-c composite equipment or bare line, and the voice-frequency line or simplex repeating coil or other drop equipment. The passage of independent composite dialing signals up to about 70 milliamperes through the two sides of the low-pass line filter does not affect carrier performance, however, so that in telephone offices having combined repeating coil and composite set equipments, used with dialing, the line filter may be located on the line side of the d-c composite set. When the carrier equipment is used to multiplex a broad-band radio link, it is necessary to separate the transmitting filters from the receiving filters, as they must be connected to the radio link transmitter and receiver, respectively. This is readily accomplished by making the proper interpanel strappings. It is generally desirable to be able to use the basic voice band beneath the first carrier channel as a telephone circuit, and for this purpose, two line filters are required, with a hybrid or 4-wire terminating circuit to provide for 2-wire operation. This equipment is provided on a separate filter panel, which is equipped with test U-links at convenient points. In 2-wire applications, if a line filter is inserted in one side of a phantom group only, phantom balance is maintained by inserting simple resistors in the other side circuit to balance the d-c resistance. These are designated line filter balance (*LFB*) resistors. However, if the voice circuit is

Figure 9. Operation of 2-coil hybrid: speech signal coming from drop circuit, resulting in no current in network when balanced

Figure 10. Operation of 2-coil hybrid: speech signal coming from demodulator circuit, resulting in no current in modulator when balanced

equipped with a 2-wire telephone repeater, a line filter must be balanced in the repeater line-balancing network with a similar 4-terminal impedance, designated line filter net (LFN), for which an identical complete line filter is used, with its high-pass side terminated in its normal impedance by a resistor.

Power Supply Circuits

Each terminal panel includes a power transformer providing heater current, and in conjunction with a rectifier tube and filter, providing plate current. Another winding of this transformer provides about 70 volts at a-c mains frequency for use in operating bells of associated subscriber sets, or other equipment, when it is not practicable to secure the usual low-frequency ringing current from an external source. This winding also provides current through a rectifier-filter circuit for transmission battery and dialing loop current for a manual or automatic telephone subscriber set. Each terminal consumes about 45 watts of a-c power.

Controls and Adjustments

Five variable controls with knobs and closely graduated dials provide all necessary adjustments required for normal lineup. These are indicated on the block diagram, Figure 2.

Transmitting Level. A grid potentiometer in the transmitting amplifier, for simultaneous adjustment of the output of speech side band and signaling channel. This permits maintaining their ratio while meeting levels other than normal required by co-ordination with other carrier systems. Normally a +12-dbm level for the speech side band test power level is transmitted to the line.

Carrier Receive Level. A control with a range of 40 db, for reducing the demodulator input to a predetermined level, therefore acting to compensate for differences between the losses of different lines.

Figure 11. Terminal for 1 channel, 9-H-2 medium-haul carrier telephone system

Figure 12. Carrier channel terminal, front cover removed to show accessibility for adjustment and maintenance

Speech Receive Level. A control with a range of 40 decibels, for adjusting the over-all circuit net loss without affecting the signaling receiver.

Signal Sensitivity. A grid potentiometer for the first tube of the signal receiving circuit, changed when required to place the received signal level at an optimum point.

Pulse Ratio. A potentiometer in the d-c portion of the signal receiving circuit, for increasing or decreasing the per cent make of the dialing impulses transmitted to the associated dial telephone switchboard equipment, to compensate for cumulative characteristic distortion resulting from pulsing relays in tandem.

In some cases it may be required to operate the signaling channel at a lower level than normal relative to the speech test power level; a tapped adjustment is provided for this, designated in Figure 2 as "SIG TRANS LEVEL ADJ".

The carrier and signaling oscillators are provided with variable-capacitance trimmers for adjusting their frequencies slightly. Modulator and demodulator circuits have low-resistance potentiometers for adjusting carrier leak to a minimum.

Test U-Links

While it is desirable to be able to break into the voice-frequency and carrier-frequency circuits to make tests and isolate sections of the equipment for trouble shooting, convenient facilities for the purpose have sometimes been skimped or omitted in an effort to keep the cost low, due to the relatively high cost of conventional telephone jacks. Inexpensive removable U-links are provided in the system described, located in the following circuits:

1. In the voice-frequency circuits between carrier and drop, for both 2-wire and 4-wire connections.
2. In the d-c leads between signaling transmitting and receiving relay circuits and the associated drop equipment, when such leads are used.
3. In the carrier-frequency circuits between the transmitting and receiving channel filters and the common bus where they are connected in parallel.
4. In the line filter circuits, between the filters and the line, carrier equipment and physical drop circuits.
5. In the modulator input circuit, where a single link may be moved between IN and OUT positions to control a 9-decibel pad.

Figure 13. Carrier channel terminal, rear view showing inert components

This pad is normally used in 2-wire drop operation, and cut out for −13 dbm 4-wire operation.

6. One pair of U-link pin jacks is provided with both jacks connected to ground, for convenience in making measurements of voltages and levels where one side of the circuit is at ground potential.

The U-link jacks will accept standard cord tips, facilitating the use of portable servicing equipment. Bridging measurements may be made without removing the U-links, by clipping to the links.

Performance Characteristics

The levels and gains shown in Table II represent limits recommended for normal use to obtain best performance. The levels are based upon a 0 dbm (1 milliwatt into 600 ohms) level applied to the 2-wire drop.

Physical Design

A relatively compact terminal assembly was designed on a single panel 19 inches wide, $8^3/_4$ inches high, containing all of the equipment for a single-channel terminal, including power supply and line filter. Thus a complete 3-channel terminal group occupies only $26^1/_4$ inches of standard rack space. On the rear side of the panel are mounted the larger components, such as filters, transformers, and potted capacitors. Smaller components, controls and vacuum tubes are mounted on vertical brackets or terminal boards on the front side, along with the wiring. The front is protected by a dust cover. An auxiliary panel is provided when it is desired to mount line filters separately, either in conjunction with a wire line or radio terminal, or at intermediate points to transfer the carrier-currents around obstacles. This panel has two forms: one mounting two line filters with related U-links, with provision for adding a 4-wire terminating hybrid set when used with a radio link; the other mounting four line filters only, used for transfer sets and telephone repeater line filter net units. This panel is 19 inches wide and $3^1/_2$ inches high.

The appearance of a single channel terminal panel is shown in the illustrations. Figure 11 is a front view with cover. The cover is removed in Figure 12, revealing the components. At the left end are the transmitting relay, terminal strip, and receiving relay, in order from the top. Adjacent are the two test U-link assemblies. On a vertical bracket are the tubes and four of the adjustable controls. A fifth control is mounted just to the left of this bracket. The power supply equipment occupies the right end of the panel. The rear of an unmounted panel is seen in Figure 13. Except for the relay socket wiring, there are no wires or cable forms on the back of the panel.

Table II

Carrier Levels	
Speech sideband transmitting level to line	+12 dbm
Signaling channel transmitting level to line	+10 dbm ±2 db
Receiving level from line, minimum	−18 dbm
Two-wire drop operation	
Net gain, drop to line	12 db
Net gain, line to drop	14 db
Total loop gain	26 db
Four-wire drop operation	
Net gain, drop to line, −13 dbm modulator input level	25 db
Net gain, line to drop, +4 dbm output level to drop	18 db
Total loop gain	43 db
Signaling Channel	
Signal receive range beyond line-up level	10 db
Range of pulse-ratio control	±10 per cent
Dial speed, pulses per second	14
Speech Channel	
Over-all channel width to 2-db rise above 1,000-cycle point: 300 to 2,700 cps; to 10 db rise: 100 to 3,000 cps.	

No Discussion

Light Steel Tower Line Design

A. A. OSIPOVICH
ASSOCIATE AIEE

THE problem of mounting costs of constructing high-voltage transmission lines has been of considerable concern to the Bonneville Power Administration. This problem assumed especial significance during the early postwar period, see Table I, when demands for many products entering into construction of high-voltage lines, and especially for steel, have kept pace with war-time demands, and in many cases exceeded it.

It was necessary, therefore, to develop a practical method to combat high cost of transmission line construction without sacrificing reliability of service. As a result, tangent-suspension and dead-end structures of the "light steel" design have been developed to carry large size conductors for 230 kv and possibly higher voltage applications.

This paper reviews the statistical and design background, as well as the physical performance of the Bonneville Power Administration's system of high-voltage transmission lines built from its inception in 1938 to date. It describes design ideas used in developing light steel structures and their application in "light steel tower lines." Results so far obtained are presented and limitations inherent in the design are discussed.

Steel Towers Form Large Component of Line Costs

The cost of steel towers in place comprises a considerable portion of the overall cost of a high-voltage transmission line. This is particularly true, percentagewise, in fairly level or rolling type of open country where right-of-way clearing and access road construction, which are also large components of line costs, are not a serious factor.

Since 1938, when construction of first lines began, the Bonneville Power Administration (BPA) has designed and built nearly 2,000 miles of steel tower lines (over 2,300 circuit miles). This total given in Table II includes lines at present under construction or ready to be contracted, as well as lines designed to the point where contracts for their steel towers have already been issued. It embraces steel tower lines of 115 kv and 230 kv, as well as of single- and double-circuit construction. It includes lines traversing all types of terrain in the states of Oregon, Washington, Idaho, and Montana.

The total cost of BPA steel tower lines, including the cost of right-of-way and clearing, represents an estimated initial investment of nearly $68,000,000. Of this amount, the cost of steel structures in place approximates $29,000,000, or 43 per cent of the total. The amount of steel in towers and foundations adds up to the impressive total of over 84,000 tons, see Table II.

It is obvious from the foregoing that any new approach to steel tower design which would result in measurable savings of dollars and tonnage would constitute a worth-while step toward achieving over-all economy of initial system investment. This is especially important in view of the fact that costs of materials and construction are still on the rise.

Conventional Designs Used by BPA in the Past

In search of ways to combat high postwar costs, BPA engineers have been constantly and critically reviewing their design practices. These practices in the past largely followed standards of design established by the electric power industry over a period of years. Single circuit structures used in BPA lines were predominantly of the so-called "rotated," self-supporting type having conductors in horizontal configuration. Double circuit towers were of the conventional, 3-crossarm type (middle crossarm extended) placing each of the circuits into a nearly vertical configuration. Both types have been developed for a variety of conductor sizes used in 115-kv and 230-kv applications. They have been designed to withstand, under actual tests, the various combinations of transverse, vertical, and longitudinal forces prescribed by the National Electrical Safety Code[1] and applicable State codes.

Tangent-Suspension Towers Predominate in a Line

As designers well know, the predominating type of a transmission line structure is the so-called "tangent-suspension" tower. This structure is used, as its name implies, in tangent or very small angle positions in the line; it usually employs a single string "suspension" type of conductor attachment which is inherently a very flexible support. Except in cases of a broken conductor or overhead ground wire, serious longitudinal strains are rarely imposed upon this type of tower. Nevertheless, standards generally accepted at the present require that suspension towers be designed and tested for broken conductor or ground wire conditions.

The tangent-suspension tower is, by its very nature, the most economical type of structure; it is, therefore, used to a maximum consistent with the terrain and alignment of a given line. BPA experience indicates that on the average this type of tower represents approximately 70 per cent of the total number of structures in the line. In open, flat, or rolling country, this percentage is even higher, more in the nature of 90 per cent, see

Paper 50-243, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted March 15, 1950; made available for printing September 5, 1950.

A. A. Osipovich is with the Bonneville Power Administration, Portland, Oreg.

The author acknowledges the assistance given by F. W. Farr who originated the light steel tower designs, and others in the BPA who helped in developing the idea and in compiling the statistical data included in this paper.

Table I. In-Place Cost of Towers and Foundations, BPA Steel Tower Lines*

Fiscal Years Inclusive	Line Miles	Tons of Steel	Costs in Cents per Pound	Remarks
1938–1945	1191.1	51,947	11.6	Indicative of low and steady costs of material and labor prevalent before and during the war. Costs are based on capital records
1946–1950	769.6	32,132	26.7	Reflecting increased costs of the postwar period. Costs are based on capital records and estimates
1938–1950			17.3	Gross average over the period of 12 years
1938–1950	1987.7	84,079		Totals

* Includes all material and labor for foundations (excavation, reinforcing steel, concrete) and towers complete in place.

Table II. It should be obvious, therefore, that any attack upon economy in the cost of steel structures in a transmission line is to be directed first of all toward this type of tower.

Dead-End Towers Are Very Costly

Another important type of structure in a line is the so-called "dead-end" or "strain" tower. This structure is ordinarily used in terminal positions, at important sectionalizing points in the line, at heavy angles, or at important crossings. Prevailing standards require that this type of structure be designed for the full effect of longitudinal tensions resulting from all conductors and overhead ground wires being broken on one side of the tower in combination with other transverse and vertical loadings resulting from standard design conditions generally accepted in a given area. By its very nature, this is a very expensive structure, especially because it requires, in order to be self-supporting, heavily designed, and expensive foundations.

This type of tower constitutes, therefore, the second focal point of attack in any attempt at economy of line construction. Quite naturally, then, BPA designers directed their next effort toward developing more economical, yet fully dependable, designs for the "dead-end" structures.

Table II. Summary of Data on BPA Steel Tower Lines

Item Number	Item	Data
1	Total line miles of steel tower construction	1987.7
	Total circuit miles of steel tower lines	2316.0
2	Total cost of lines (including clearing, roads, material and labor)	$67,688,369
	Cost of steel in place, including foundations	$28,943,465
	Cost of steel in place in per cent of total cost	43%
	Total tons of steel	84,079
3	Gross average per cent of tangent structures in all lines	70%
	Average estimated per cent of tangent structures in flat country lines	90%
4	Circuit mile years of operation of all BPA steel tower lines	25,470
5	Estimated tons of steel saved by use of light steel to date	12,840
	Estimated saving of federal funds to date	$4,168,460

War-Time Experience Leads to New Design Ideas

The basic approach of BPA designers in their effort to effect economy in steel tower construction, without sacrificing reliability, resulted from an early wartime experience. The problem at hand was to design a 230-kv circuit paralleling on the same right-of-way a "standard" steel tower line previously built between Grand Coulee Dam and the Covington Substation, located in the Seattle load area. Because of the scarcity of steel and the insistence of the War Production Board that its use be brought to a minimum, it was decided to place upon wood structures those portions of this line (110 miles out of a total of 183) which were located in open, easily accessible and fairly flat terrain of low elevation.[2,3] Naturally, it was not economically practicable to design the 230-kv wood structures of the "tangent-suspension" type for the "broken-conductor" loading conditions for which the initial "standard" steel tower line was constructed. Hence, these structures were designed primarily for the usual standard transverse and vertical loadings, but only for limited longitudinal loads. Experience with this line, in operation since 1944, and with a total to date of nearly 1,900 mile-years of operating 230-kv wood lines built since then, indicates nearly a perfect record of mechanical performance. This fact, and the parallel record of nearly 25,500 mile-years, Table II, of operating the entire BPA system with only one or two physical failures (at that not entirely attributable to loading) proved the reliability and safety of using "flexible" structures and, thus, formed the basis for the theory of our light steel tower line designs.

"Light Steel Tower Line" Defined

A light steel tower line is defined, in BPA usage, as a line in which the predominating "tangent-suspension" structures have been designed for conditions analogous to those used in designing wood pole lines. In other words, these structures in a light steel tower line are designed primarily for transverse and vertical loads resulting from the ice, wind,

Figure 1. Typical light steel tangent-suspension towers, rotated type
230-kv design for 500,000 circular mil copper equivalent steel-reinforced aluminum cable conductors

Figure 2. Typical light steel dead end structures, lattice-pole type
230-kv design for 500,000-circular-mil copper equivalent steel-reinforced aluminum cable conductors

and temperature conditions usually prevailing in the Pacific Northwest. As an inherent consequence of steel design, these structures also are capable, under certain conditions which will be discussed later, of resisting fairly large longitudinal unbalanced loads.

The light-steel tangent-suspension towers, as designed by BPA, are of the rotated type; they do not differ in outward appearances from the "rotated," single circuit towers of the standard design. Like their standard protypes, they are fitted to the topography of the tower site and to varying heights required in a transmission line by a system of body- and tower-leg extensions, see Figure 1.

The analogy with wood pole lines also is carried in a light steel tower line to the design of "dead-end" and "heavy angle" structures. To effect economy, these structures in a light steel tower line are no longer self-supporting towers. They are designed as steel lattice pole frames capable of withstanding the columnar action resulting from all prescribed design loads imposed upon them. To meet the full longitudinal and transverse strains resulting from maximum design loading conditions, these steel poles are adequately guyed much in the same manner as their wood pole counterparts would be, see Figure 2. In this design, the amount of steel in the structures and the quantities of material in their foundations are reduced considerably, as is also, the amount of labor and the total cost required to erect these structures, Table II.

Intermediate types of towers, such as double-suspension and medium- to large-angle structures, employed in a light steel tower line are of the same standard type as used in all other BPA lines. In other words, where long spans are required, or power line, railroad, highway, and similar important crossings occur, the heavier standard types of towers are used.

Consequently, while differing outwardly from the BPA standard steel tower lines only in the appearance of dead-end, heavy-angle and transposition structures, the light steel tower line provides the economy of initial construction approaching that of wood pole lines, yet affords the advantages of minimum maintenance and longer life usually associated with steel tower construction.

It may be in order at this time to underscore a point which is probably self-evident by now; namely, that the light steel tower line idea has been applied to date only to single circuit designs. However, light steel tower lines using steel reinforced aluminum-cable conductors of both the 500,000 circular mil and the 800,000 circular mil copper equivalent have been designed and constructed at the present time. Designs of structures for each conductor size are naturally associated with a maximum working tension which is considered to be most economical for the conditions under which the given conductor is used. Therefore, the 500,000 circular mil and the 800,000 circular mil conductors each require their own set of light steel structures.

It should be pointed out also that a light steel tower line is not a constant, but a fluctuating concept in that the per-mile tonnage of any given line is naturally dependent on terrain, alignment, and other factors characteristic of the area which it traverses. Hence, the percentage of light steel tangent-suspension and lattice-pole dead-end structures, as well as the total per-mile tonnage for every light steel tower line, are variables, see Table III.

Economy Studies Made in 1946

Early studies which ultimately resulted in the acceptance of the idea of light steel tower line designs date back to 1946.[4,5] At that time comparisons were made of initial construction costs, as well as of average annual costs over a 50-year life period for different types of line construction.

In these studies, each one of the structure types under consideration was applied to actual profiles of lines with somewhat similar terrain but differing in density of population and development of

Table IV. General Data on BPA Transmission Lines; Fiscal Years 1939–1950, Inclusive

Item Number	Remarks	Data	Remarks
1	Line miles in operation	3738.8	All types and voltages; wood and steel lines
	Circuit miles in operation	4036.9	
2	Total number of steel towers	8,305	All BPA steel lines
3	Per cent of tangent-suspension structures	70%	Gross average for all types and voltages of steel tower lines
	Per cent of dead-end structures	8%	
	Per cent of other structures	22%	

roads, utilities, and so forth. Results indicated that the initial cost of light steel tower lines is not much higher than that of the most economical wood pole lines. Yet, on the basis of average annual costs for a 50 year-life period, the light steel tower lines are indicated to be the more economical, Table V. It is admitted, of course, that this relation may be upset by differing cost trends in the steel and wood industries. This, however, has not been proved the case to date; at least not to the point of upsetting the basic conclusion.

New Designs Subjected to Full Size Tests

Basic designs and preparation of detail plans for the various types of structures usually employed in a line proceeded apace after the conclusion was reached to adopt the new light steel design for future BPA lines where conditions would warrant its application. These designs were made for "heavy" loading conditions, namely: 1/2 inch radial ice, 8 pounds wind at 0 degree Fahrenheit.

The first contract for light steel was placed with the American Bridge Company in 1948. A full scale test of a "tangent-suspension" tower designed for the 500,000 circular-mil copper equivalent steel-reinforced aluminum-cable conductor was performed under this contract in November of that year. This test has proved the following to the complete satisfaction of both the BPA designers and the steel fabricators:

1. That this light steel structure will carry all transverse design loads with a minimum safety factor of 1.5.
2. That it will carry all vertical design

INITIAL INVESTMENT — MAINTENANCE & OPERATION COSTS

loads with a minimum safety factor of 2.0.

3. That, when otherwise not subjected to appreciable wind and ice loads, it will resist an unbalanced longitudinal load at one of the outside conductors in excess of 6 kips.

A few improvements which were indicated by the results of the full scale tests, as well as some minor changes which resulted from field experiences in erecting the structures, were incorporated into the final designs of the initial series of structures (using 500,000 circular-mil conductors).

Since that time, a full series of light steel structures have been designed for use with 800,000 circular-mil copper equivalent conductors. These structures are so designed that they will accommodate insulation and clearance requirements for future operation at 287 kv.

Light Steel Tower Lines Savings Appraised

A number of light steel tower lines have been designed by BPA engineers during the last three years. Some of these have been constructed and are in operation. Others are at present under construction; and major materials have been ordered for a few more; see Table III.

It now is estimated that for the lines shown in Table III, a total saving of over 12,800 tons of steel has been effected directly attributable to the use of light steel instead of the standard steel designs. This saving in tonnage, coupled with related savings in costs of transporting, handling in the yards, and erecting in the field, would result in an estimated saving of nearly $4,170,000. These savings in material and funds are, of course, considerable by any standards.

To these savings must be added others which have not, or cannot be accurately evaluated. Under this heading would come:

1. Savings to contractors due to greater use of mechanized equipment in erecting light steel structures because of their reduced total weights, which in turn makes possible assembly of larger structure sections on the ground and smaller number of lifts per structure; hence, greater productivity in terms of structures erected per day or week for a given crew.

2. Faster erection permits shorter construction periods; this, in turn, makes possible earlier energization and the advancement of the time when a line begins to return revenue.

A word of caution seems in order at this point. Light steel tower line designs should be applied judiciously with respect to both terrain and climatic conditions prevailing in an area. These designs should not be used at high elevations, in places inaccessible through a considerable portion of the year, or in areas known to be subject to heavy ice and sleet storms. Also, they should not be used where future plans call for installation of overhead ground wires, as they are not designed for this purpose.

Studies Continue for Perfecting Structural and Mechanical Designs

As indicated previously, future lines of the Bonneville Power Administration through areas free from severe icing and lightning will be predominantly of the light steel design. This does not mean that BPA studies and explorations in the field of structural and mechanical design, as related to high-voltage lines, will not continue. Studies now are oriented toward further perfection of the light steel designs for conductor sizes mentioned in this paper and, perhaps, larger ones. Studies also are in progress for lines of higher voltages than 287 kv, both in standard steel and light steel designs, as well as for single and "bundle" conductors. Investigations have been started toward development of steel structures which would permit a practical combination of the light steel idea, with the need for overhead ground wire protection in areas of high lightning frequency.

Use of structural aluminum in transmission line applications is being studied co-operatively with manufacturers and fabricators. Efforts also are under way toward establishing a more logical correlation between structural designs and hardware development for larger conductors and higher voltage applications.

Conclusion: No Troubles Anticipated in Operating Light Steel Lines

It is, of course, too early to draw upon operating experience with our newly designed light steel tower lines. However, we have been careful to apply this design only in those portions of our various lines where conditions for its use are appropriate. Therefore, we do anticipate the same nearly trouble-free mechanical performance of light steel tower lines as we had with operating and maintaining the BPA system since its inception.

Discussion

O. D. Evans (Oklahoma Gas and Electric Company, Oklahoma City, Okla.): This paper raises again the long and much-discussed question of whether or not to design steel tower transmission lines for one, or more, conductors or shield wires broken. A perusal of technical literature on the subject of steel tower design leads to the conclusion that nearly all companies design steel tower lines for at least one, and in many cases two, conductors or shield wires broken. The fact that wood pole tangent structures are not designed for broken cables is one of the reasons they are considerably less in initial cost than are steel tower lines.

A cost estimate, made by us for a short section of 66-kv double circuit line in 1948, indicated that we could expect to pay over twice as much for a steel tower line as for a wood pole line if we were to consider two conductors (or one conductor and one shield wire) broken, which we deemed necessary for this particular line. A saving could have resulted in the steel tower design had we eliminated the broken conductor (or shield wire) requirement, but the steel tower design could never have been made competitive in initial cost with the wood pole line; however, consideration of rights-of-way procurement, appearance, and permanency of the standard steel tower design dictated its use and this line was recently constructed and placed in operation. It is recognized, however, that the differential between steel-tower and wood-pole designs would tend to decrease as the voltage ascended to 287 kv which the paper discusses.

The author is careful to point out that his light steel tower designs should not be used in areas subject to heavy ice and sleet storms. This, in itself, would eliminate a large portion of this country from using light steel tower designs; yet, wood pole lines have been used in these areas for years. A conductor or shield wire break in a well-designed modern transmission line is not likely to occur, and future breaks should be even less likely as our knowledge of conductor and shield wire vibrations and the phenomena of "galloping" conductors is enhanced. Airplanes will tend to present a constantly increasing menace, but it is not believed economically feasible to design for airplanes hitting electric power transmission

lines. It is extremely unlikely that an airplane will ever hit a line in open country and, if one does, it will probably break more than two cables.

Suppose one or two cables are broken on one of the light steel tangent tower designs—what would happen? There would be an initial impact on the tower after which the cable would probably slip through the suspension clamp. One way to lessen this impact would be to use "J-bolt" type suspension clamps and not to tighten the nuts on these clamps too securely. The clamp is required merely to support the cable and any changes in longitudinal tension, other than a conductor break, would probably be taken care of by a deflection of an insulator string in the case of a conductor or by the shield wire attachment if a sufficiently flexible assembly is used. The impact, if sufficiently heavy, might deform the steel crossarm member without further damage to the tower; in such cases, wood crossarm members could be used for temporary repairs until steel members had been fabricated.

Should a cable break seriously damage one or more towers, which seems unlikely considering the inherent longitudinal strength that would result from a satisfactory transverse and vertical load design, temporary wood pole structures could be hurriedly erected to provide service. This could be done in such a way as to leave the towers free for maintenance work.

As indicated in the author's paper, the light steel tower design will inherently withstand fairly large longitudinal loads, much more so than will wood pole lines. It seems to me, therefore, that the question boils down as to why the designer is using the steel tower design. If it is to obtain longitudinal strength for broken cables, and this consideration outweighs everything else, then the so-called standard steel towers must be used. If a tower line is being used for any other reason, then careful consideration should be given to the light steel tower designs. In the tower line recently constructed by our company, mentioned earlier in this discussion, a large part of the line was in the city limits of Oklahoma City and a tower collapse would entail heavy property damage and possible loss of life.

The lattice-pole type angle and dead-end structures used in the light steel tower design particularly fascinates me. This design has all the advantages of the standard steel tower design and at approximately half the cost. I can see no reason why this design should not be used in all designs except in (or near) towns where rights-of-way for guying are too expensive or cannot be obtained.

In designing lightning-resistant lines, the effect of wood as an insulator for lightning strokes must be taken into consideration when comparing costs. The lowered ground resistance that the steel tower will have over the wood pole structure will partially offset this difference in lightning impulse strength of the structure.

Finally, the structure life also enters into the cost analysis. From one of the author's references it was ascertained that 25 years was used as the expected life of a wood pole line and 50 years as the expected life of a steel tower line. Many conditions, particularly soil conditions, enter into the life of a particular line. Fifty years seems to be the accepted life value of a steel tower line, but many companies use 30 years expected life for a creosoted pine wood pole, and some even use 40 years.

The engineer must be ever alert to new ideas and improvements. It is predicted that the light steel tower designs discussed by the author will become rather common in the years to come as our knowledge of conductor failures is advanced and as the depletion of our supply of wood poles increases the cost of wood pole lines.

Jordan Lummis (Southern California Edison Company, Los Angeles, Calif.): A transmission tower is so much a creature of its designers assumptions that any attempt to compare the structures of two engineers runs squarely against this subjective difficulty. Mr. Osipovich has made a definite study of his own structures which have yielded him economic results but other designers should be warned that the results can be applied to their own structures only with caution. The assumptions used in tower engineering may be divided into two broad groups; those pertaining to design and those pertaining to loadings. None of them are completely sound and many are wide of the truth.

In the case of design assumptions, the first are those defining the maximum tension and compression limits and these are strictly a matter of personal opinion. Limiting tensions used in tower design vary from 18,000 to 25,000 pounds per square inch. In the case of compression we have a wide choice of column formulas, and we must also assume end conditions, minimum slenderness, and minimum thickness. One column formula in common use permits a compressive stress of 7,000 pounds per square inch under the same conditions that an equally common formula permits 12,000 pounds per square inch. Again, one common specification limits slenderness-ratio in redundant members to 200 while another permits 275. In one case increasing minimum thickness from 1/8 inch to 3/16 inch increased the weight of a tower more than 16 per cent.

In the case of the common type of tower Mr. Osipovich is concerned with, the distribution of torsion becomes a very important factor because this style of structure is statically indeterminate in a high degree. An out-and-out assumption of the amount of torsion carried by each face of the tower can be, and often is, made. More exact analyses can be based on the principle of virtual force, least work, or limit design but even these are approximate approaches.

Loading assumptions also can vary greatly and this condition is made more complex by lack of agreement on wire tension. However, assume tension fixed for the moment and consider the other assumptions that must be made; the line angle, the span length, the vertical load, the wind velocity, the number of broken wires, the reduction in tension caused by broken wire, the effect of impact, and any special conditions required for safe construction. Now note that most of these assumptions are permutations of maximum tension which is commonly assumed anywhere in the range of 25 to 50 per cent of wire strength.

Another very important assumption which does not fall into either of the preceding classifications will involve the nature of the steel itself. Steel companies now commonly furnish tower steel in "structural" and "high elastic" grades. The greater strength of the "high elastic" steel usually results in economies when used for legs, cross arms, and other highly stressed members. Yet many fabricators roll, but will not guarantee, "structural" grade steel exceeding the requirements of the higher grade. In any case, the assumption of limiting basic stress will be an important one.

Mr. Osipovich's "light" tower results from a reduction in loading assumptions. It is probably possible to arrive at the same result by changing design assumptions. In a recent case an old 66-kv tower was compared to a new tower based on less conservative design assumptions. The duty of each tower was nominally the same but the more conservative tower weighed 3,000 pounds while the less conservative weighed 1,800 pounds.

While many assumptions have been noted, many more could be. The effect of these assumptions have only been hinted, yet they are far reaching and sometimes surprising as may be seen in the case where the minimum allowable size of members was reduced from 3/16 inch to 1/8 inch. This structure performed admirably in test but in service many of the thin members broke from vibration and the reduction of thickness meant failure within six months of members that would otherwise last indefinitely.

B. R. Murphy (The Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Canada): If the chief purpose for considering light steel tower designs is to reduce transmission line costs, this must be proved by operating experience in any given system.

Transmission engineers should, however, give serious consideration to the suggestion that the loading introduced by the assumption of a broken conductor be disposed of. Elimination of this loading as well as the omission of ground cables are basic differences between light steel tower designs and so-called conventional designs. Developments and operating experience which affect the suggested trend to less steel are:

1. Should a broken conductor occur, suspension insulators swing to relieve considerably the unbalanced pull on the tower.

2. Experience indicates that conductors, especially steel-reinforced aluminum cable with fast switching, simply do not break or burn off. In a hurricane, nine 230-kv conductors and six ground wires did not break when either one or two towers in three parallel 230-kv single-circuit lines were twisted and flattened practically always on their own foundations. One of about five towers lay somewhat along the line. During the winter of 1949–50, a rather severe sleet storm moved across Michigan and Ontario. In Ontario most of the copper, and like conductors, at the rural distribution level and lower voltages came to ground. Steel-reinforced aluminum-cable conductors seldom, if ever, broke. They did hold up trees in some cases and poles were broken in other cases.

3. Very short spans between dead ends and at a 90-degree corner using two 45-degree angles with conductors dead ended can result in high unbalances in tension

Figure 1. 110-kv 1939 type single-circuit suspension tower

Conductors, 3-477,000 circular mil steel reinforced aluminum cable; ground cable, $1^3/_{16}$-inch galvanized steel; normal span, 1,000 feet; maximum tangent span, 1,350 feet; maximum angle in line, 3 degrees; voltage, 110,000

Loads: I. Vertical, 1,200 pounds at point 1 and 2,200 pounds at each of three points 2 and 3. II. Horizontal-transverse, 1,500 pounds at point 1 and 2,200 pounds at each of three points 2 and 3. III. Horizontal-longitudinal, 4,000 pounds at point 1 or 3,750 pounds at one point 2 or 7,500 pounds at point 3. IV. Dead load. Combine I and IV with II or III or use twice I alone. Load II contains allowance for wind on tower and 3-degree turn in line

which may affect closely designed light steel towers.

4. If ground cables can be eliminated in a design for light steel towers, then use of these towers becomes territorial and depends on the climatic conditions.

5. A fabricated structure and one assembled in part in the field differs from a wood pole structure or steel structure, welded into large units as used in Sweden. Changes in factors of safety will tend to make their use and comparative reliability possible. The cost of failure in closely designed structures should be accounted.

Designers and operators in Ontario have been using light steel towers widely in the 120-kv field since 1939, see Figure 1 of this discussion. It has since been found from experience that the connection between horizontal members of the footing and the leg were not properly detailed and, secondly, that the uplift characteristics were not entirely satisfactory in clay. This structure, with minor modifications, is still being used.

Wood structures have not been used yet in Ontario for 230-kv construction, but their use has been considered.

Policy is involved in reducing the amount of steel used in transmission lines towards some light steel tower design. Some policy makers may say that the end cost of a kilowatt-hour is not importantly involved in an even fairly long high-voltage transmission line. It would be interesting to know the actual weight of a light steel tower design and of a heavier modern alternative design.

Would Mr. Osipovich use guyed dead-end towers at the entrance to a transformer station?

Some engineers might class "A" frame towers as light steel towers. Both structurally and operationally the reasons now are available why such types should be avoided. It is true that an "A" frame can be designed with considerable resistance to loads along the line; however, it is necessary to give rather careful attention to the details of stringing the first two ground wires on such lines. After that it is possible to erect three or more conductors successfully.

Summarizing, it appears that the advantages in using light steel tower designs will be territorial and will be governed by climatic conditions.

While there are still some fairly obvious reasons why twin wood poles seem to stand up well under extraordinary wind loads, nevertheless, there is no attempt in this discussion to explain why twin poles should not be used.

A. A. Osipovich: The author appreciates the interest shown and the effort expended by O. D. Evans, J. Lummis, and B. R. Murphy in preparation of their written discussion and by Dr. E. L. Kanouse who restricted his comment to oral remarks at the session.

It appears to the author that all the discussors have agreed upon one important point. This point is that the long existing problem of correlating practicability and economy still remains a very important one for the industry in relation to design of transmission line structures. These discussors also underscore a related fact that no solution proposed for this problem can escape the danger of being regarded as controversial.

The author agrees with Mr. Lummis that designing a set of transmission line structures is a highly "individualistic" endeavor. It is so because no two engineers will think alike with respect to basic design assumptions, or will apply the same criteria in the use of basic materials. It is so, also, because no two important transmission systems ever present an identical combination of the numerous factors (such as terrain, climate, load, voltage, and so forth) which enter prominently into determination of the type of design to be employed in any given case.

It is true, as Mr. Murphy suggests, that the degree to which a given design idea accomplishes the objective of combining practicability with economy is usually determined through the long test of years of performance. However, the author feels that in a young system such as that of the Bonneville Power Administration, a synthesis of design experience and line performance, related to a substantial number of mile-years, can and should be logically relied upon for the establishment of a set of design assumptions, such as were arrived at in the economic studies which preceded the adoption of the "light steel" design by BPA.

Table I of this discussion combines information contained in the slides shown during the presentation of the paper to give the comparison in weight and costs between several comparable types of "light" and "standard" structures placed side by side as part of two parallel circuits on the same right-of-way.

The weight and cost information shown in this table is based on unit prices taken from contracts which covered both "light" and "standard" structures. These unit prices were contained in low bids of February 3, 1949, for materials, and February 2, 1950, for construction of the Chehalis-Covington 230-kv line. The tabulation shows in all cases a considerable advantage in favor of "light" over "standard" structures.

The author wishes to underscore again the point made in the paper that the "light steel" designs have their limitations and, therefore, are not applicable under conditions encountered in those parts of the country where icing and lightning conditions are severe. However, where these designs are properly applicable, they result not only in the immediate savings of the initial investment, when compared with "standard steel" designs, but also in the long range economy based on annual costs when compared with functionally equivalent wood

Table I

Tower Type	Conductor Height Above Ground, Feet	Total Weight of Steel in Structure and Grillage Foundation: Light, Pounds	Total Weight of Steel in Structure and Grillage Foundation: Standard, Pounds	Total Cost Erected: Light	Total Cost Erected: Standard
Tangent-suspension	62	7,828	13,331	$1,864.80	$2,796.15
Medium-angle	63/65	14,041	21,287	3,892.35	4,610.60
Dead end	72	17,548	36,625	5,872.50	7,641.00

pole lines for which the initial investment may be smaller.

There is one more important factor, which was not mentioned in the original paper, favoring the use of "light" steel designs in a large transmission system such as that of the Bonneville Power Administration. This may be designated as the "diversity" factor. When a transmission system has a number of high capacity circuits paralleling each other between important generation and load centers; when such a system is also interconnected with a number of other systems in the area to form a regional pool of power; and when the most important load and distribution centers in the region are provided with at least a 2-way feed; —then the elements of "risk" involved in losing a circuit is reduced to a minimum and such a "risk" becomes economically justifiable. Hence, the decision to use "light steel" designs for circuits paralleling the initial "standard steel" circuits (or "back-bone" circuits as they are called in BPA) in areas where past performance of the initial lines has shown a high degree of reliability. That such a calculated "risk" is justified, especially in the light of resulting economies both as far as material and costs are concerned, is one of the points which was intended to be brought out by the author in his paper.

Finally, the author finds encouragement in the statement of Mr. Murphy that "transmission engineers should give serious consideration to the suggestion that the loading introduced by the assumption of a broken conductor be disposed of." Also encouraging is the prediction made by Mr. Evans that "the light steel tower designs . . . will become rather common in years to come, as our knowledge of conductor failures is advanced. . . ." Both of the above remarks are indicative of the sentiment evidentally present among transmission line engineers, and fully shared by BPA engineers, to the effect that some modification of the rules of "mechanical" design contained in the National Electrical Safety Code is perhaps forthcoming.

As indicated in the paper, BPA is continuing its studies and explorations in the field of structural, mechanical, and electrical design, especially as related to higher voltages. This work includes a new set of structures recently developed which can carry overhead ground wires loaded in accordance with "light steel design" principle.

The reaction of transmission line engineers to this paper will spur our development work. As soon as further practicable results are evident, BPA will share its experience with the industry.

Steady-State Waves on Transmission Lines

D. L. WAIDELICH
MEMBER AIEE

THE increased use of nonsinusoidal waves on transmission lines such as, for example, the location of faults on the lines[1] by means of repeated pulses, has made it desirable to consider how the response of the lines to the applied nonsinusoidal waves may be obtained. The transient response of the line has been presented in a number of previous papers[2,3] but the steady-state response seems to have been neglected. It is the purpose of this paper to consider various methods of obtaining the steady-state response of transmission lines to applied nonsinusoidal waves and also to give several experimental results for purposes of comparison. These methods apply as well to plane electromagnetic waves propagating in a good dielectric which is isotropic.

In making the mathematical analysis it is assumed that the frequencies are sufficiently high so that certain simplifications may be made. For example, in the operational expression for the characteristic impedance Z_0 of the transmission line

$$Z_0=\sqrt{(R+Lp)/(G+Cp)}$$
$$=\sqrt{\frac{L}{C}}\left[1+\frac{1}{p}\left(\frac{R}{2L}-\frac{G}{2C}\right)+\ldots\right] \quad (1)$$

where R, L, G, C are the resistance, the inductance, the conductance, and the capacitance of the line for a unit length, it is assumed that only the first term in the series is necessary. From this point on it will then be assumed that $Z_0=\sqrt{L/C}$. Similarly for the propagation constant γ the operational expression is

$$\gamma=\sqrt{(R+Lp)(G+Cp)}$$
$$=p\sqrt{LC}\left[1+\frac{1}{p}\left(\frac{R}{2L}-\frac{G}{2C}\right)-\frac{1}{8p^2}\left(\frac{R}{L}-\frac{G}{C}\right)^2+\ldots\right] \quad (2)$$

and only the first two terms in the series will be used so that

$$\gamma=(p/V)+a \quad (3)$$

where $V=1/\sqrt{LC}$ = velocity of propagation of the waves and

$$a=\frac{R}{2}\sqrt{\frac{C}{L}}+\frac{G}{2}\sqrt{\frac{L}{C}}=\text{attenuation constant}$$

To show how the various methods may be used to determine the steady-state waves appearing on a transmission line, a particular example will be employed. This example is that of a line with a square-wave generator connected to one end while the other end is open-circuited. The voltage e_R at the open end is to be determined. The generator is assumed to have zero internal impedance, and the generated voltage e_g is shown in Figure 1. The steady-state transform[4] E_g of the generated voltage is

$$E_g=\frac{E}{p}(1-\epsilon^{-pT/2})^2 \quad (4)$$

The steady-state transform E_R of the voltage at the open end of the line is

$$E_R=\frac{E_g}{\cosh \gamma l} \quad (5)$$

where l is the length of the line. The voltage is then

$$e_R=\frac{1}{2\pi j}\int_W \frac{\epsilon^{pt}E(1-\epsilon)^{-pT/2}dp}{p(1-\epsilon^{-pT})\cosh\left[(pl/V)+al\right]} \quad (6)$$

where W is a certain path of integration[4] in the p-plane. If the substitutions $p'=pT$, $\beta=(l/VT)$, $\alpha=al$ and $\theta=(t/T)$ are made in equation 6,

$$\frac{e_R}{E}=\frac{1}{2\pi j}\int_W \frac{\epsilon^{p'\theta}(1-\epsilon^{-p'/2})^2dp'}{p'(1-\epsilon^{-p'})\cosh(p'\beta+\alpha)} \quad (7)$$

The primes now will be omitted.

The first method of evaluating the integral of equation 7 uses the poles within the path W, sometimes called the driving function or "voltage" poles, and leads to the usual Fourier series for the voltage e_R. These poles are $p=\pm j2\pi n$ where n is a positive integer or zero. When the residues at each one of these poles are added, the result is

$$\frac{e_R}{E}=\sum_{n=1}^{\infty} Y_n \sin(2n\pi\theta-\delta) \quad (8)$$

which is summed over all odd integral values of n and in which

$$Y_n=4/n\pi\sqrt{\sinh^2 a+\cos^2 2n\pi\beta}$$

and

$$\delta=\tan^{-1}\left[(\tanh a)(\tan 2n\pi\beta)\right]$$

The even harmonic voltages are absent in e_R since there are none in the applied square wave of voltage. The result of equation 8 is useful in determining the amount of harmonic voltages present, but is of very little use in determining the actual waveforms present except in some very special cases. One such special case is that for $\alpha=0$ and $\beta=1/6$ which means that the losses in the transmission line are zero and that a wave on the line travels the length of the line in one-sixth of the period of the applied square wave. From equation 8 the open end voltage is

$$\frac{e_R}{E}=2\left[\frac{4}{\pi}\sum_{n=}^{\infty}\frac{\sin 2n\pi\theta}{n}\right]-\left[\frac{4}{\pi}\sum_{n=1}^{\infty}\frac{\sin 6n\pi\theta}{n}\right] \quad (9)$$

Paper 50-244, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23-27, 1950. Manuscript submitted March 13, 1950; made available for printing August 30, 1950.

D. L. WAIDELICH is with the University of Missouri, Columbia, Mo.

Figure 1. The square-wave voltage e_S of the generator

Figure 2. The open-end voltage e_R of the transmission line with no attenuation ($\alpha=0$)

which are summed over all odd integral values of n. The first series of equation 9 is a square wave of amplitude $2E$ and period T, while the second is a square wave of amplitude E and period $(T/3)$. The resulting wave is shown in Figure 2, and this may be called the sum function of the series of equation 9.

For circuits with concentrated parameters the sum function of the Fourier series may be obtained without difficulty by using the poles outside the path W, sometimes called the system-function or "impedance" poles. In most circuits these poles are finite in number and thus lead to an expression with a finite number of terms. This approach was tried as the second method of evaluating the integral of equation 7. The poles are $-(\alpha/\beta)\pm j(m\pi/2\beta)$, where m is an odd positive integer. Since there are again an infinite number of poles, the resulting expression[4] is an infinite series somewhat resembling a Fourier series. When $0<\theta<1/2$, the voltage at the open-circuited end is

$$\frac{e_R}{E}=\frac{1}{\cosh\alpha}+\sum_{m=1}^{\infty}\frac{(-1)^{\frac{m+1}{2}}4\epsilon^{-\sigma\theta}}{\beta(\sigma^2+\mu^2)}A_m \quad (10)$$

in which

m = an odd positive integer

$$A_m=\frac{\sigma[\sin\mu\theta+\epsilon^{-\sigma/2}\sin\mu(\theta-1/2)]+\mu[\cos\mu\theta+\epsilon^{-\sigma/2}\cos\mu(\theta-1/2)]}{[1+2\epsilon^{-\sigma/2}\cos(\mu/2)+\epsilon^{-\sigma}]}$$

$\sigma=\alpha/\beta$

$\mu=m\pi/2\beta$

Again this is useful in determining waveforms only in some special cases such as the one used in the preceding paragraph. If $\alpha=0$ and $\beta=1/6$, the result is a Fourier series similar to equation 9 but not the same series.

$$\frac{e_R}{E}=1+\frac{4}{\pi}\sum_{m=1}^{\infty}\frac{\sin 3\pi m\theta}{m}-\frac{4}{\pi}\sum_{m=1}^{\infty}(-1)^{\frac{m-1}{2}}\frac{\cos 3\pi m\theta}{m} \quad (11)$$

in which m is an odd positive integer. The second term of equation 11 is a square wave of amplitude E and period $(2T/3)$, while the third term is a square wave of the same amplitude and period but shifted in phase by $(T/6)$. When the three terms of equation 11 are added, the result is again the wave of Figure 2.

The third method involves the use of steady-state convolution or "faltung" integrals.[5] Let $A(t)$ be the voltage at the open end of the line when a unit voltage is suddenly applied[3] to the generator end of the line, and $A(t)=A(\infty)+R(t)$ where $A(\infty)$ is a constant approached by $A(t)$ as t becomes very large and then $R(t)$ approaches zero as t becomes large. The form of the steady-state convolution integral to be used is:

$$e_R=A(\infty)e_s(t)+\frac{d}{dt}\int_0^T e_s(t-\tau)P(\tau)d\tau \quad (12)$$

where

$$P(t)=\sum_{n=0}^{\infty}R(t+nT)$$

and n is a positive integer or zero. In the example at hand, from $\theta=0$ to $\theta=\beta$, $A(t)=0$, and from $\theta=m\beta$ to $(m+2)\beta$, where m is an odd positive integer,

$$A(t)=2\epsilon^{-\alpha}\left[\frac{1+(-1)^{\frac{m-1}{2}}\epsilon^{-(m+1)\alpha}}{1+\epsilon^{-2\alpha}}\right] \quad (13)$$

Then

$$A(\infty)=2\epsilon^{-\alpha}/(1+\epsilon^{-2\alpha}) \quad (14)$$

and also from $\theta=0$ to $\theta=\beta$, $R(t)=-2\epsilon^{-\alpha}/(1+\epsilon^{-2\alpha})$, and from $\theta=m\beta$ to $\theta=(m+2)\beta$, where m is an odd positive integer

$$R(t)=(-1)^{\frac{m-1}{2}}\frac{2\epsilon^{-(m+1)\alpha}}{1+\epsilon^{-2\alpha}} \quad (15)$$

Then for the special case of $\beta=1/6$, from $\theta=0$ to $\theta=1/6$,

$$P(t)=\frac{-2\epsilon^{-\alpha}}{(1+\epsilon^{-3\alpha})(1+\epsilon^{-4\alpha})}$$

and from $\theta=m/6$ to $\theta=(m+2)/6$ where m is an odd positive integer

$$P(t)=(-1)^{\frac{m-1}{2}}\frac{2\epsilon^{-(m+1)\alpha}}{(1+\epsilon^{-3\alpha})(1+\epsilon^{-4\alpha})} \quad (16)$$

With the aid of equations 12, 14, and 16 and in the interval from $\theta=0$ to $\theta=1/6$:

$$e_R=\frac{2E(-\epsilon^{-\alpha}+\epsilon^{-3\alpha}+\epsilon^{-5\alpha})}{(1+\epsilon^{-4\alpha})}$$

Figure 3 (left). The open-end voltage e_R of the transmission line with attenuation ($\alpha=0.2$)

Figure 4. The calculated output voltage of the line for an applied square wave

from $\theta=1/6$ to $\theta=1/3$

$$e_R=\frac{2E(e^{-\alpha}+e^{-3\alpha}+e^{-5\alpha})}{(1+e^{-6\alpha})} \tag{17}$$

and from $\theta=1/3$ to $\theta=1/2$

$$e_R=\frac{2E(e^{-\alpha}+e^{-3\alpha}-e^{-5\alpha})}{(1+e^{-6\alpha})}$$

The values of e_R for the second half cycle from $\theta=1/2$ to $\theta=1$ are the negatives of those given in equation 17. When $\alpha=0$, the receiving end voltage as calculated from equation 17 is again the wave of Figure 2. For a line with losses the wave is not quite so symmetrical as is shown in Figure 3 for the case of $\alpha=0.2$.

The fourth method depends upon an extension and summation of the various waves obtained from the response $A(t)$ to a unit voltage. Consider

$$A(t)=\frac{1}{2\pi j}\int_{W_1}\frac{e^{p\theta}(1-e^{-p/2})^2dp}{p(1-e^{-p})\cosh(p\beta+\alpha)} \tag{18}$$

where W_1 is the usual path of integration for the inverse Laplacian transform and is to the right and parallel to the imaginary axis. Equation 18 should be compared with equation 7. By use of the series:

$$\frac{(1-e^{-p/2})^2}{1-e^{-p}}=1-2e^{-p/2}+2e^{-p}-2e^{-3p/2}+\ldots.$$

and

$$\frac{1}{\cosh(p\beta+\alpha)}=2e^{-(p\beta+\alpha)}-2e^{-3(p\beta+\alpha)}+2e^{-5(p\beta+\alpha)}-\ldots.$$

the response to the unit voltage is

$$A(t)=\sum_{m=1}^{\infty}A_m(t) \tag{19}$$

where m is an odd integer and

$$A_m(t)=\frac{1}{2\pi j}\int_{W_1}(-1^{\frac{m-1}{2}}2e^{-m(p\beta+\alpha)})\times[1-2e^{-p/2}+2e^{-p}-2e^{-3p/2}+\ldots.]\times\frac{e^{-p\theta}}{p}dp$$

In the problem used as an example $\beta=1/6$. Consider one of the terms in the series for $A(t)$, say

$$A_3(t)=(-2)\frac{1}{2\pi j}\int_{W_1}e^{-3(p/3+\alpha)}\times[1-2e^{-p/2}+2e^{-p}-\cdots]\frac{e^{p\theta}}{p}dp$$

which represents a square wave beginning at $\theta=1/2$ and with an amplitude of $2e^{-3\alpha}$. This square wave should be continued or extended back to $\theta=0$. Each one of the square waves for each of the A_m's should be extended back in a like manner to $\theta=0$. All of the square waves may then be summed to give the required steady-state output voltage e_R. The result is for $0<\theta<1/6$.

$$\frac{e_R}{E}=-2e^{-\alpha}+2e^{-3\alpha}+2e^{-5\alpha}+2e^{-7\alpha}-2e^{-9\alpha}-2e^{-11\alpha}-2e^{-13\alpha}+\ldots.$$

$$=\frac{-2e^{-\alpha}+2e^{-3\alpha}+2e^{-5\alpha}}{1+e^{-6\alpha}}$$

for $1/6<\theta<1/3$

$$\frac{e_R}{E}=\frac{2e^{-\alpha}+2e^{-3\alpha}+2e^{-5\alpha}}{1+e^{-6\alpha}} \tag{20}$$

for $1/3<\theta<1/2$

$$\frac{e_R}{E}=\frac{2e^{-\alpha}+2e^{-3\alpha}-2e^{-5\alpha}}{1+e^{-6\alpha}}$$

These results are identical with equation 17 and will thus give the waves of Figures 2 and 3.

Experimental Results

In the experimental work a square-wave generator with a high output impedance was used with a length of *RG-8/U* coaxial cable, and the voltage across the other end of the cable was observed with a high-impedance cathode-ray oscilloscope. For this purpose then both ends of the cable were effectively open circuited. Under these conditions the operational voltage at the receiving end is

Figure 6. The calculated output voltage of the line for an applied pulse wave

$$E_R=\frac{Z_0V_g}{R_g\sinh\gamma l} \tag{21}$$

where V_g is the transform of the generator voltage and R_g is the output impedance (considered a pure resistance) of the generator. By the use of the fourth method given in the analysis section for $\beta=1/12$, it is found that for

$$0<\theta<1/12,\quad \frac{e_R}{E}=\frac{Z_0}{R_g}\left[\frac{-2e^{-\alpha}-2e^{-3\alpha}-2e^{-5\alpha}}{1+e^{-6\alpha}}\right]$$

for $1/12<\theta<1/4$

$$\frac{e_R}{E}=\frac{Z_0}{R_g}\left[\frac{2e^{-\alpha}-2e^{-3\alpha}-2e^{-5\alpha}}{1+e^{-6\alpha}}\right]$$

for $1/4<\theta<5/12$

$$\frac{e_R}{E}=\frac{Z_0}{R_g}\left[\frac{2e^{-\alpha}+2e^{-3\alpha}-2e^{-5\alpha}}{1+e^{-6\alpha}}\right] \tag{22}$$

for $5/12<\theta<1/2$

$$\frac{e_R}{E}=\frac{Z_0}{R_g}\left[\frac{2e^{-\alpha}+2e^{-3\alpha}+2e^{-5\alpha}}{1+e^{-6\alpha}}\right]$$

where E is the peak value of the applied square wave.

The calculated receiving end voltage e_R for $\alpha=0.2$ and $\beta=1/12$ is shown in Figure 4, and the experimental wave form is that of Figure 5. Evidently the two

Figure 5 (left). The experimental output voltage of the line for an applied square wave

Figure 7 (right). The experimental output voltage of the line for an applied pulse wave

half waves of the applied square wave were not exactly equal because some dissymmetry is noticeable in the figure. Also some overshoot is visible and this might be caused in part by the characteristics of the oscilloscope used and also by the fact that the velocities, attenuations, and terminations of the cable are not those assumed in the analysis.

The action of repeated pulses[4] on a transmission line also was studied. If E is the transform of the applied repeated pulses, the output voltage e_R will be calculated for a transmission line effectively open circuited at both ends. Again using the fourth method given in the analysis section for $\beta=1/8$, it is found that

at $\theta=1/8$

$$e_R=\frac{Z_0E}{R_gT}\left(\frac{2\epsilon^{-\alpha}}{1-\epsilon^{-2\alpha}}\right)$$

at $\theta=3/8$

$$e_R=\frac{Z_0E}{R_gT}\left(\frac{2\epsilon^{-3\alpha}}{1-\epsilon^{-2\alpha}}\right) \tag{23}$$

at $\theta=5/8$

$$e_R=\frac{Z_0E}{R_gT}\left(\frac{2\epsilon^{-5\alpha}}{1-\epsilon^{-2\alpha}}\right)$$

at $\theta=7/8$

$$e_R=\frac{Z_0E}{R_gT}\left(\frac{2\epsilon^{-7\alpha}}{1-\epsilon^{-2\alpha}}\right)$$

The output voltage would then be four pulses per period as shown in Figure 6 which was calculated for $\alpha=0.2$. The experimental wave form is shown in Figure 7, and it was obtained using a pulse length of 0.5 microsecond and a pulse repetition rate of 84.3 kc per second on a 957-foot length of *RG 8/U* coaxial cable. The velocity of propagation may be obtained from

$$V=l/\beta T=1.97\times10^8 \text{ meters per second} \tag{24}$$

and the velocity factor, that is, the ratio of the velocity of the pulses on the line and the velocity of light in space, is 65.7 per cent. From equation 24, at $\theta=n/8$ where n is 1, 3, 5, or 7, e_R is proportional to $\epsilon^{-n\alpha}$. If $\ln e_R$ is plotted versus n, the result should be a straight line of slope $(-\alpha)$. This was done with the waveform of Figure 7, and a straight line resulted with a slope of -0.188. The experimental value of $\alpha=0.188$, and the attenuation constant $a=(\alpha/l)=0.1964\times10^{-3}$ neper per foot or 0.1703 decibel per 100 feet of cable.

Transients in Coupled Inductance-Capacitance Circuits Analyzed in Terms of a Rolling-Ball Analogue

P. C. MAGNUSSON
MEMBER AIEE

AN ELECTRIC system consisting of two inductance-capacitance loops with negligible resistance, and inductively coupled together, has a dynamical analogue in the form of a freely rolling ball on an elevated surface. The time integrals of the loop currents are used as the co-ordinates, with the loop currents themselves analogous to the velocity of the ball along those co-ordinates. The magnetic field energy becomes analogous to the kinetic energy of the ball if the scales of the co-ordinates are made proportional to the square roots of the corresponding self inductances, and are inclined with respect to each other at the angle whose cosine is the coefficient of coupling.

The height of the surface, and hence the potential energy of the ball, is made proportional to the dielectric field energy at each co-ordinate position. Contours of dielectric field energy are concentric ellipses, the axes of which also are known as the normal co-ordinates. General motion of the ball on the surface may be resolved into two independent component motions parallel to those axes.

Geometrical representation of the ball path and of mathematical quantities associated with it aids in the interpretation of transients in systems with two degrees of freedom. By suitable choice of vertical and horizontal scales, a physical model may be designed with a known ratio between its time scale and that of the original circuit.

Advances of the last two to four decades in the study of linear transients have been primarily in the refinement and extension of mathematical procedures, notably operational calculus and the Laplace transform. Energy is not dealt with directly in applying those techniques, and its encompassing role in relating physically a particular set of initial conditions to the corresponding response tends to be neglected. The rolling-ball analogue, which emphasizes the significance of energy in the physical problem, gives a geometrical presentation which unifies the transient behavior of a lumped-constant system.

Two inductance-capacitance loops inductively coupled together will be used as the basic example. Two degrees of freedom make a system considerably more complicated than one with a single degree of freedom, and are sufficient to give a good insight into multiple degree of freedom cases in general.

Derivation of Analogue

Two physical systems are said to be analogous if they give rise to mathematically similar equations of motion. The analogue developed here is that of a freely rolling ball on a curved surface, wherein the path followed by the ball corresponds, in terms of appropriately oriented and scaled co-ordinates in the base plane, to the response of the original system.

Since the equations of motion are derivable by Lagrange's method[1] from the potential and kinetic energies, the parallel nature of analogous systems appears in those quantities. With comparison of expressions for energy in the two systems as the plan of attack, the analogue may be conveniently derived.

Let the quantity of electricity or charge q be chosen as the dynamical co-ordinate of an inductance-capacitance (L-C) circuit; the energy stored in the capacitor may be readily expressed in terms of q, and the energy stored in the magnetic field is proportional to the square of the current, which is the time rate of change of q, or dq/dt.

The potential energy of the ball is proportional to the height of the surface, which is a function of location in the base-plane co-ordinates. Kinetic energy, on the other hand, is proportional to the square of the velocity, or time derivative of position along the co-ordinates. It follows that analogies should be sought between kinetic energy and magnetic field energy, and between potential energy and dielectric field energy.

It is assumed that the vertical component of the ball velocity in the analogue is small compared with the horizontal component, so that the latter may be considered equal in magnitude to the total velocity. A further assumption is that gyroscopic effects in the ball are negligible.

Generalized co-ordinates which are directly proportional to linear displacement will be used as measures in the base plane of the analogue in this discussion. Determination of the correct vertical and horizontal scales in a physical model to obtain a prescribed ratio of time scales

Figure 1. Circuit for which analogue is derived

Paper 50-245, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23-27, 1950. Manuscript submitted March 7, 1950; made available for printing August 29, 1950.

P. C. MAGNUSSON is Assistant Professor of Electrical Engineering, Oregon State College, Corvallis, Oreg.

Part of the study and research for this paper was sponsored by the Engineering Experiment Station at Oregon State College.

between the model and the electric circuit is discussed in the Appendix.

Magnetic Field and Kinetic Energies

The energy stored in the magnetic field at any instant in the circuit shown in Figure 1 is:

$$W_L = (^1/_2)(L_1 i_1^2 + L_2 i_2^2 - 2M_{12} i_1 i_2) = (^1/_2)\left[L_1\left(\frac{dq_1}{dt}\right)^2 + L_2\left(\frac{dq_2}{dt}\right)^2 - 2M_{12} \times \frac{dq_1}{dt}\frac{dq_2}{dt}\right] \quad (1)$$

Kinetic energy is independent of the direction of the velocity vector, hence the generalized co-ordinates representing q_1 and q_2 in the analogue should be scaled with respect to those quantities so that a given magnitude of velocity will always correspond to the same amount of magnetic field energy. The first step towards obtaining this correspondence is to define the generalized co-ordinates x_1 and x_2 as follows:

$$\left.\begin{aligned} x_1 &= q_1\sqrt{L_1} \\ x_2 &= q_2\sqrt{L_2} \end{aligned}\right\} \quad (2)$$

Differentiation of equations 2 yields:

$$\left.\begin{aligned} \frac{dx_1}{dt} &= \frac{dq_1}{dt}\sqrt{L_1} \\ \frac{dx_2}{dt} &= \frac{dq_2}{dt}\sqrt{L_2} \end{aligned}\right\} \quad (3)$$

Substitution of equations 3 into equation 1 gives the following:

$$W_L = (^1/_2)\left[\left(\frac{dx_1}{dt}\right)^2 + \left(\frac{dx_2}{dt}\right)^2 - 2\left(M_{12}/\sqrt{L_1L_2}\right)\frac{dx_1}{dt}\frac{dx_2}{dt}\right] \quad (4)$$

The coefficient of coupling k may be substituted here.

$$k_{12} = M_{12}/\sqrt{L_1L_2} \quad (5)$$

$$W_L = (^1/_2)\left[\left(\frac{dx_1}{dt}\right)^2 + \left(\frac{dx_2}{dt}\right)^2 - 2k_{12}\frac{dx_1}{dt}\frac{dx_2}{dt}\right] \quad (6)$$

The generalized velocities dx_1/dt and dx^2/dt are vectors in the co-ordinate plane, and will be assumed to be separated by angle β, defined as follows:

$$\cos\beta = -k_{12} \quad (7)$$

This situation is sketched in Figure 2; the vector sum of the component velocities dx_1/dt and dx_2/dt is, by the law of cosines:

$$|dx_1/dt + dx_2/dt| = \sqrt{\left(\frac{dx_1}{dt}\right)^2 + \left(\frac{dx_2}{dt}\right)^2 + 2\frac{dx_1}{dt}\frac{dx_2}{dt}\cos\beta} \quad (8)$$

Hence

$$W_L = (^1/_2)|dx_1/dt + dx_2/dt|^2 \quad (9)$$

Figure 2. Vector addition of velocity components

Thus if the co-ordinates representing q_1 and q_2 in the analogue are laid out at angle β with respect to each other, and with scales (in terms of coulombs) proportioned in accordance with equations 2, the kinetic energy of the ball will be analogous to the total magnetic field energy of the coupled L-C circuits.

Dielectric Field and Potential Energies

The energy stored in the dielectric form in capacitors C_1 and C_2 is:

$$W_C = (^1/_2)(C_1e_1^2 + C_2e_2^2) \quad (10)$$

$$= (^1/_2)[(q_1^2/C_1) + (q_2^2/C_2)] \quad (11)$$

Substitution of the generalized co-ordinates defined in equations 2 gives the following expression:

$$W_C = (^1/_2)[(x_1^2/L_1C_1) + (x_2^2/L_2C_2)] \quad (12)$$

The potential energy of the ball in the analogue is proportional to the height h of the surface, hence h is proportional to the right-hand side of equation 12.

Transformation to Normal Co-ordinates

When the motion is analyzed in terms of the oblique co-ordinates used thus far (x_1,x_2), a set of two simultaneous equations results, both of which involve two dependent variables. With W_C a quadratic function of the x_1,x_2 co-ordinates, it is possible to select a set of rectangular co-ordinates in terms of which each equation of motion contains only one dependent variable. These are known as the normal co-ordinates,[1] and will be designated by y_1, y_2.

Orientation of Normal Co-ordinates

Contours of the W_C surface, or loci of constant values of W_C, prove to be ellipses and, as will be seen, the normal co-ordinates are parallel to the axes of these ellipses. Co-ordinate y_1 will be considered as displaced by angle α from x_1, as shown in Figure 3, and angle α will next be evaluated.

$$\left.\begin{aligned} y_1 &= x_1\cos\alpha + x_2\cos(\beta-\alpha) \\ y_2 &= -x_1\sin\alpha + x_2\sin(\beta-\alpha) \end{aligned}\right\} \quad (13)$$

Equations 13 are solved for x_1 and x_2.

$$\left.\begin{aligned} x_1\sin\beta &= y_1\sin(\beta-\alpha) - y_2\cos(\beta-\alpha) \\ x_2\sin\beta &= y_1\sin\alpha + y_2\cos\alpha \end{aligned}\right\} \quad (14)$$

Equations 14 are substituted into equation 12.

$$W_C = [1/(2\sin^2\beta)]\{(1/L_1C_1)[y_1^2 \times \sin^2(\beta-\alpha) - 2y_1y_2\sin(\beta-\alpha) \times \cos(\beta-\alpha) + y_2^2\cos^2(\beta-\alpha)] + (1/L_2C_2)[y_1^2\sin^2\alpha + 2y_1y_2 \times \sin\alpha\cos\alpha + y_2^2\cos^2\alpha]\} \quad (15)$$

If y_1 and y_2 are to be parallel to the axes of the ellipse, the sum of the terms involving the product y_1y_2 must be zero, hence:

$$-(1/L_1C_1)\sin(\beta-\alpha)\cos(\beta-\alpha) + (1/L_2C_2)\sin\alpha\cos\alpha = 0 \quad (16)$$

This reduces as follows:

$$-\sin 2(\beta-\alpha) + [(L_1C_1)/(L_2C_2)]\sin 2\alpha = 0$$

$$-\sin 2\beta\cos 2\alpha + \cos 2\beta\sin 2\alpha + [(L_1C_1)/(L_2C_2)]\sin 2\alpha = 0$$

$$\tan 2\alpha = (\sin 2\beta)/\{[(L_1C_1)/(L_2C_2)] + \cos 2\beta\} \quad (17)$$

Equations of Motion

Expressions for W_C and W_L in terms of the normal co-ordinates may be substituted into Lagrange's equation[1] to obtain the equations of motion.

$$\left.\begin{aligned} &\partial(W_C - W_L)/\partial y_1 - d[\partial(W_C - W_L)/\partial dy_1/dt]/dt = 0 \\ &\partial(W_C - W_L)/\partial y_2 - d[\partial(W_C - W_L)/\partial dy_2/dt]/dt = 0 \end{aligned}\right\} \quad (18)$$

Equation 15 states W_C in terms of the normal co-ordinates, but it may be simplified by subtracting equation 16.

$$W_C = [1/(2\sin^2\beta)]\{(1/L_1C_1)[y_1^2 \times \sin^2(\beta-\alpha) + y_2^2\cos^2(\beta-\alpha)] + (1/L_2C_2)[y_1^2\sin^2\alpha + y_2^2\cos^2\alpha]\} \quad (19)$$

An expression for W_L in terms of dy_1/dt and dy_2/dt, the generalized velocities along y_1 and y_2, may be obtained by substituting equations 14 (with velocities dx_1/dt, dx_2/dt, dy_1/dt and dy_2/dt substituted for co-ordinates x_1, x_2, y_1, and y_2) into equation 6. After simplification of the trigonometric forms, the following is obtained:

$$W_L = (^1/_2)\left[\left(\frac{dy_1}{dt}\right)^2 + \left(\frac{dy_2}{dt}\right)^2\right] \quad (20)$$

Upon substituting equations 19 and 20 into equations 18, these equations of motion result:

$$\left.\begin{aligned} &(1/\sin^2\beta)[(1/L_1C_1)\sin^2(\beta-\alpha) + (1/L_2C_2)\sin^2\alpha]y_1 + d^2y_1/dt^2 = 0 \\ &(1/\sin^2\beta)[(1/L_1C_1)\cos^2(\beta-\alpha) + (1/L_2C_2)\cos^2\alpha]y_2 + d^2y_2/dt^2 = 0 \end{aligned}\right\} \quad (21)$$

Equations 21 may be solved by the following substitutions:

$$\left.\begin{aligned} y_1 &= A_1\sin\omega_1 t + B_1\cos\omega_1 t \\ y_2 &= A_2\sin\omega_2 t + B_2\cos\omega_2 t \end{aligned}\right\} \quad (22)$$

These values are found for ω_1 and ω_2:

$$\left.\begin{aligned}\omega_1 &= (1/\sin\beta)\times\\ &\sqrt{(1/L_1C_1)\sin^2(\beta-\alpha)+(1/L_2C_2)\sin^2\alpha}\\ \omega_2 &= (1/\sin\beta)\times\\ &\sqrt{(1/L_1C_1)\cos^2(\beta-\alpha)+(1/L_2C_2)\cos^2\alpha}\end{aligned}\right\} \quad (23)$$

The quantities A_1, A_2, B_1, and B_2 in equations 23 are arbitrary constants; they are found to be the following in terms of the initial values of y_1, y_2, dy_1/dt and dy_2/dt:

$$\left.\begin{aligned}y_1(0) &= B_1\\ y_1'(0) &= \omega_1 A_1\\ y_2(0) &= B_2\\ y_2'(0) &= \omega_2 A_2\end{aligned}\right\} \quad (24)$$

In terms of the initial voltages on the capacitors and the initial currents in the coils, these initial conditions are (substituting equations 2 into 13):

$$\left.\begin{aligned}y_1(0) &= e_1(0)C_1\sqrt{L_1}\cos\alpha+\\ &\quad e_2(0)C_2\sqrt{L_2}\cos(\beta-\alpha)\\ \frac{dy_1}{dt}(0) &= i_1(0)\sqrt{L_1}\cos\alpha+\\ &\quad i_2(0)\sqrt{L_2}\cos(\beta-\alpha)\\ y_2(0) &= -e_1(0)C_1\sqrt{L_1}\sin\alpha+\\ &\quad e_2(0)C_2\sqrt{L_2}\sin(\beta-\alpha)\\ \frac{dy_2}{dt}(0) &= -i_1(0)\sqrt{L_1}\sin\alpha+\\ &\quad i_2(0)\sqrt{L_2}\sin(\beta-\alpha)\end{aligned}\right\} \quad (25)$$

The voltages across the capacitors may be found as functions of time by substituting equations 22 into 14, and the latter into equations 2.

$$\left.\begin{aligned}e_1 &= [1/(C_1\sqrt{L_1}\sin\beta)][\sin(\beta-\alpha)\times\\ &\quad (A_1\sin\omega_1 t+B_1\cos\omega_1 t)-\\ &\quad \cos(\beta-\alpha)(A_2\sin\omega_2 t+\\ &\quad B_2\cos\omega_2 t)]\\ e_2 &= [1/(C_2\sqrt{L_2}\sin\beta)][\sin\alpha(A_1\times\\ &\quad \sin\omega_1 t+B_1\cos\omega_1 t)+\cos\alpha(A_2\\ &\quad \sin\omega_2 t+B_2\cos\omega_2 t)]\end{aligned}\right\} \quad (26)$$

These results agree with those obtained by operational solution of the loop circuital equations, and are in a form adapted to graphical interpretation.

Analysis of Analogue

An isometric projection of part of a typical analogue surface is shown in Figure 4. (Data are listed in Table I.) The surface, which has been proportioned in accordance with the theory just developed, is a paraboloid with elliptical cross-section, and extends upwards indefinitely on all sides. The path followed by a freely rolling ball on this surface will have projections on the oblique base co-ordinates x_1,x_2 which will correspond identically, except for change in time scale, to the oscillations of the respective parts of the circuit. These co-ordinates have been scaled in terms of charge; corresponding capacitor voltages may be found by dividing the charge by the respective capacitance.

Paths of motion projected onto the base plane may be described, in the terminology of mathematical physics, as paths of the representative point of configuration space (2-dimensional here); such paths are sketched in Figures 3 and 6 for two particular sets of initial conditions. Capacitors C_1 and C_2 are charged to some initial voltage; switches 1 and 2 (Figure 1) are closed simultaneously in the first case, while in the second example, switch 1 is closed shortly before switch 2. Since the circuit is nondissipative, the total energy of the system remains constant at the initial value, and the W_C contour corresponding to this initial energy (the same in both examples) is shown in Figures 3, 4, and 6. The axes of this elliptical contour are colinear with the normal co-ordinate axes.

Example with Initial Charges but No Initial Current

The geometric framework within which the ball path is plotted in Figure 3 may be constructed in this manner: The co-ordinate axes x_1 and x_2 are laid out at angle β (equation 7) with respect to each other, and angle α is found from equation 17, after which the axes of the normal co-ordinates may be drawn. The initial charges are scaled on the x_1 and x_2 axes, with oa equal to $q_1(0)\sqrt{L_1}$, (or $e_1(0)\ C_1\sqrt{L_1}$), and ob equal to $q_2(0)\sqrt{L_2}$ (or $e_2(0)\ C_2\sqrt{L_2}$). A parallelogram is formed by drawing bc parallel to oa, and ac parallel to ob. The value of W_C at point c represents the initial energy, and the contour previously mentioned therefore passes through point c. (Drawing of the contour is not an essential part of this graphical construction, however.) Line cd is drawn perpendicular to normal co-ordinate y_1, and ce, perpendicular to y_2. Comparison with the first and third of equations 25 indicates that od is $y_1(0)$, and equal to B_1, the amplitude of the cosine oscillatory motion in the analogue with frequency of $\omega_1/2\pi$, and that oe is $y_2(0)$, equal to B_2, the amplitude of the cosine motion with frequency of $\omega_2/2\pi$. Because there are no initial currents in this example, the coefficients of the sine terms, A_1 and A_2, are zero.

The amplitude of each frequency component appearing in e_1 may be found by drawing lines df and eg parallel to the x_1 axis.

$$e_1 = [of/(C_1\sqrt{L_1})]\cos\omega_1 t+ [og/(C_1\sqrt{L_2})]\cos\omega_2 t \quad (27)$$

$y_2(0)$	6.35×10^{-3} coulomb $\sqrt{\text{henry}}$	Equations 13, 25; Figure 6 oz
$dy_2/dt(0)$	1.30 ampere $\sqrt{\text{henry}}$	Equations 13, 25

Similarly, the amplitudes of the two components in e_3 may be found by drawing dj and ek parallel to the x_1 axis.

$$e_3 = [oj/(C_3\sqrt{L_3})]\cos\omega_1 t + [ok/(C_3\sqrt{L_3})]\cos\omega_2 t \quad (28)$$

Comparison may be made with equations 26; the correctness of the corresponding terms may be readily checked by applying the sine law to Figure 3. Plots of e_1 and e_3 as functions of time are given in Figure 5.

The range of the path of motion was initially limited by the W_C contour corresponding to the initial energy of the system, but by equations 22, with the values now found for the arbitrary constants, the range is further limited to the rectangle $ckmn$. This rectangle is symmetric about both the y_1 and y_2 axes. If the ratio ω_1/ω_2 is irrational, the path of motion will eventually pass infinitesimally close to every point within this rectangle; should the frequency ratio be rational, the path will assume a repetitive pattern.

It should be noted that for a given value of W_C, an infinite number of inscribed rectangles is possible, one corresponding to each point x_1, x_2 along the contour. Thus any ratio between the amplitudes of the two components may be obtained by appropriate selection of the initial conditions, and if the "starting point" is on one of the normal co-ordinate axes, the amplitude of one frequency component is reduced to zero.

Example with Initial Charges and One Initial Current

The initial current in this example will be obtained by closing switch 1 a short time τ before zero time, but leaving switch 2 open until t equals zero. Then the L_1C_1 portion of the circuit will act as an independent circuit during that period, and the current and voltage will vary as follows:

$$\left.\begin{aligned} e_1 &= e_1(-\tau)\cos[(t+\tau)/\sqrt{L_1C_1}] \\ i_1 &= -e_1(-\tau)\sqrt{C_1/L_1}\sin[(t+\tau)/\sqrt{L_1C_1}] \end{aligned}\right\} \quad -\tau \leq t \leq 0 \quad (29)$$

In terms of the analogue, this amounts to motion constrained to a path parallel to the x_1 axis, and is shown in Figure 6 by cp, where the co-ordinate system and point c were located as in the preceding example. At t equals zero, and switch 2 closes, the constraint is removed, and motion is characterized by two degrees of freedom. The projection of point p onto the normal co-ordinate axes yields, as before, the amplitudes of the cosine oscillations, that is, or equals B_1 and os equals B_2. Substituting the second of equations 29 into 25 and 24, with t equal to zero, yields:

$$\left.\begin{aligned} A_1 &= -e_1(-\tau)[\sqrt{C_1}/\omega_1]\sin(\tau/\sqrt{L_1C_1})\cos\alpha \\ A_2 &= e_1(-\tau)[\sqrt{C_1}/\omega_2]\sin(\tau/\sqrt{L_1C_1})\sin\alpha \end{aligned}\right\} \quad (30)$$

The resultant magnitudes D_1 and D_2 of the sine and cosine waves of the same frequencies are:

$$\left.\begin{aligned} D_1 &= \sqrt{A_1^2+B_1^2} \\ D_2 &= \sqrt{A_2^2+B_2^2} \end{aligned}\right\} \quad (31)$$

In Figure 6, D_1 is represented by od', and D_2 by oe'. The complete rectangle $c'k'm'n'$ may then be drawn. This rectangle proves to be one inscribed within contour W_C.

The magnitudes of the cosine components appearing in e_1 and e_2 may be found, as in the preceding example, by projecting points r and s parallel to the x_1 or x_2 axis until the other axis is intersected. Similarly, if A_1 and A_2 are plotted along the y_1 and y_2 axes, projections may be made to determine the magnitudes of the sine components in e_1 and e_2.

Effect of Resistance

Resistance in an electric circuit produces a voltage instantaneously proportional to the current. The analogous effect in the rolling-ball system, with two degrees of freedom, is a force which is a function of the velocity. In general, however, the force vector is not colinear with the velocity vector, nor are the magnitudes proportional. Exact analysis of the resistance force field is complicated, and its physical realization in a rolling-ball analogue would be difficult if not impossible.

From the standpoint of the complete solution as a function of time, the presence of resistance in a single-loop resistance-inductance-capacitance circuit attenuates the oscillation exponentially and lengthens the period of oscillation beyond what it would be if the resistance were zero. The latter effect is significant only when the resistance is high enough to cause rather heavy attenuation. Still greater resistance will cause the period of oscillation to become imaginary, and the transient currents or voltages become sums of two real exponential functions. Qualitatively it may be said that results in a coupled 2-loop circuit are similar.

Extension to Other Systems

The general principle developed in this paper was that of deriving a co-ordinate system and an elevated surface in terms of which the kinetic and potential energies of a rolling ball will correspond rigorously to the magnetic and dielectric field energies of an electric circuit. This plan should be applicable to any dynamically conservative electrical or mechanical system with two degrees of freedom. In some instances it may be more advantageous to make the magnetic field energy analogous to the potential energy, and the dielectric field energy analogous to kinetic energy. This interchange of the quantities which are to correspond to each other, as compared to the arrangement used in the body of this paper, is similar to the concept of "dual" circuits.

If the potential energy is considered as associated simply with a contour on the co-ordinate plane, and gravity and the elevated surface are dispensed with, generalization to three degrees of freedom is possible; then potential energy contours would be surfaces (concentric ellipsoids, in the case of a strictly linear system) rather than lines.

Although the example treated in this paper was a linear system, this is not essential for the representation of a system by a rolling-ball analogue. Solutions in closed form for nonlinear systems with two degrees of freedom are usually out of the question, but the potential energy surface and the contour of total system energy for specified initial conditions can still be of considerable aid in determining the nature of the motion. Trajectories plotted on the surface from numerical solutions of the equations of motion will further clarify the situation. Instability will occur in some nonlinear systems if the energy associated with the initial conditions exceeds a certain critical value, and the analogue surface and initial energy contour depict this situation.

Conclusions

The rolling-ball analogue, a concept which should prove helpful in gaining insight into the transient behavior of two degree of freedom systems generally, has been derived for a system of two inductance-capacitance loops inductively coupled together. This analogue consists of a curved surface, elevated above a co-ordinate plane, on which a spherical ball may roll freely.

The dielectric field energy stored in the capacitors is made analogous to the potential energy of the ball, which is propor-

Figure 3. Ball path analogous to circuit behavior when switches are closed simultaneously. Circled points correspond to intervals of 0.001 second in circuit response

Figure 5 (right). Capacitor voltages (Figure 1) as functions of time when switches are closed simultaneously

tional to the height of the surface above a reference plane. The magnetic field energy of the coupled circuit is made analogous to the kinetic energy of the rolling ball. Velocity of the ball is therefore analogous to current, and the co-ordinates represent the time integral of current (or charge) in each loop. These must be scaled in proportion to the square roots of the respective self inductances if the kinetic-magnetic energy equivalence is to be valid. The presence of mutual inductance further requires that these co-ordinates be oblique rather than perpendicular to each other, and the angle separating them is the inverse cosine of the coefficient of coupling.

Contours of the analogue surface are concentric ellipses, and motion may be resolved into two characteristic components of motion parallel to the axes of those ellipses, which also are known as the normal co-ordinates. Various initial conditions may be plotted in the co-ordinate field, and the relative magnitudes of the component harmonic motions visualized.

Physical models may be built in a convenient size, with a known ratio of time scale relative to the original system. Such models, used in conjunction with "top view" plots of ball paths, would probably furnish the best educational means of applying the theory developed in this paper.

Appendix. Scaling of a Physical Model

It is of interest to know the scales of various dependent variables in a physical model in relation to the analogous quantities in the actual circuit, and to note the effect of making the two time scales different. This information will aid in actually designing such a model, which would be of assistance in demonstrating the transient behavior of two degree of freedom systems.

Analogue Proportions for Unity Time Scale Ratio

The problem of determining the proportions which a physical model should have will be attacked by comparing the expressions for energy in the two systems. The kinetic energy of the ball is given by the following:

$$W_K = (1/2)\left[(w/g)v^2 + J(v/r)^2\right] \tag{32}$$

Here w is the weight of the ball, r the radius, and J, the moment of inertia. For a solid spherical ball, (moment of inertia equals $(2/5)(w/g)r^2$), this reduces to:

$$W_K = (1/2)(1.4w/g)v^2 \tag{33}$$

Velocity v may be replaced by the vector sum of du_1/dt and du_2/dt, component velocities separated by angle β.

$$W_K = (1/2)(1.4w/g)\left|\frac{du_1}{dt} + \frac{du_2}{dt}\right|^2 \tag{34}$$

The corresponding term in the analogue, magnetic field energy stated in terms of generalized co-ordinates, is:

$$W_L = (1/2)\left|\frac{dx_1}{dt} + \frac{dx_2}{dt}\right|^2 \tag{9}$$

Let the height h of the elevated surface be defined as follows:

$$h = (1/2)(b_1u_1^2 + b_2u_2^2) \tag{35}$$

Here b_1 and b_2 are constants which will be evaluated later. The potential energy W_P is:

$$W_P = wh = w(1/2)(b_1u_1^2 + b_2u_2^2) \tag{36}$$

The analogous quantity, dielectric field energy, is:

$$W_C = (1/2)\left[(x_1^2/L_1C_1) + (x_2^2/L_4C_4)\right] \tag{12}$$

Both the potential and kinetic energies in the model are directly proportional to the weight of the ball, yet the period of oscillation of such a system is independent of that weight, hence it is not essential that the potential and kinetic energies of one system equal numerically the corresponding energies in the other for them to have identical responses as functions of time. Comparing the ratio of W_L/W_C to W_K/W_P will suffice to determine the constants b_1 and b_2 in terms of the circuit parameters.

$$W_L/W_C = \left|\frac{dx_1}{dt} + \frac{dx_2}{dt}\right|^2 / \left[(x_1^2/L_1C_1) + (x_2^2/L_4C_4)\right] \tag{37}$$

$$W_K/W_P = (1.4w/g)\left|\frac{du_1}{dt} + \frac{du_2}{dt}\right|^2 / \left[w(b_1u_1^2 + b_2u_2^2)\right]$$

$$= (1.4/g)\left|\frac{du_1}{dt} + \frac{du_2}{dt}\right|^2 / (b_1u_1^2 + b_2u_2^2) \tag{38}$$

Figure 4. Isometric projection of part of analogue surface

Figure 6 (right). Ball path analogous to circuit behavior when switch 1 is closed 0.003 second before switch 2. Circled points correspond to intervals of 0.001 second

Let the b's be defined as follows:

$$b_1 = (1.4/g)/(L_1C_1) \tag{39}$$
$$b_2 = (1.4/g)/(L_2C_2)$$

Substitution of equations 39 into 38 yields the following:

$$W_K/W_P = \left|\frac{du_1}{dt} + \frac{du_2}{dt}\right|^2 / [(u_1^2/L_1C_1) + (u_2^2/L_2C_2)] \tag{40}$$

At any instant the following pairs of ratios will be equal if the two systems are behaving the same with respect to time:

$$\left.\begin{aligned} x_2/x_1 &= u_2/u_1 \\ \frac{dx_1}{dt}/x_1 &= \frac{du_1}{dt}/u_1 \\ \frac{dx_1}{dt}/x_1 &= \frac{du_2}{dt}/u_1 \end{aligned}\right\} \tag{41}$$

Under these circumstances, the right-hand sides of equations 37 and 40 will equal each other, but they would not do so if b_1 and b_2 had not been defined as stated in equation 39.

Since g has the dimensions of $(length)/(time)^2$, and the product LC has the dimensions of $(time)^2$, the b's have the dimensions of $(length)^{-1}$, and are measures of the curvatures of the surface along the u_1 and u_2 axes.

Use of Nonunity Time Scale Ratio

Application of the foregoing to a numerical example, the data for which are given in Table I, will demonstrate that in many instances it is impractical to obtain a 1-to-1 time correspondence between a rolling-ball analogue and the original circuit. Letting g equal 32.2 feet per second squared, b_1 is found to be 7.23×10^4 inverse feet, and b_2 is 4.35×10^4 inverse feet. This value of b_1 would require that at u_1 equal to 0.1 foot and u_2 equal to zero, h would be 36.15 feet. Thus for a relatively small value of u_1 the basic assumption that the horizontal component of velocity be always essentially equal to the total magnitude of velocity would be grossly violated.

This difficulty may be overcome without making the model of microscopic dimensions by having a time scale of the model longer than that of the circuit. Increasing each LC product by the factor of 10^4 would, according to the theory of vibrations, increase the periods of oscillation by the square root of that factor, or 10^2; diminishing the b's by the factor of 10^{-4} will have the same effect. In this case a time scale ratio of 200 (multiply the b's by 2.5×10^{-4}) would be suitable, for at u_1 equal to one foot and u_2 equal to zero, h would be 0.0905 foot, and at u_1 equal to zero and u_2 equal to one foot, h would be 0.0544 foot.

Relative scales of u_1 and u_2 are indicated by equations 2. For the values of L_1 and L_2 given in Table I, if one foot along u_1 is to be equivalent to 0.05 coulomb, the same distance along u_2 would be equivalent to $0.05 \sqrt{L_1/L_2}$ or 0.0447 coulombs. In terms of the capacitor voltages which would result from those charges, for the values of C_1 and C_2 given in the same table, one foot along u_1 would correspond to $0.05/C_1$ or 667 volts on C_1, and one foot along u_2 would correspond to $0.0447/C_2$ or 447 volts on C_2.

Current is the time derivative of charge, but account must be taken of the time scale ratio in scaling current with respect to velocity in the analogue. Hence a velocity of one foot per second along u_1 is analogous to 0.05×200 or 10 amperes in the L_1C_1 loop, and the same magnitude of velocity along u_2 is analogous to 0.0447×200 or 8.94 amperes in the L_2C_2 loop. (The corresponding magnetic field energies prove to be equal, just as one foot per second velocity requires the same kinetic energy regardless of its direction.)

Model Construction

To construct a model on which the rolling ball would follow a path which would correspond closely to the calculated circuit behavior for several cycles would, of course, necessitate great care in shaping the analogue surface, a degree of care perhaps comparable to that taken in grinding lenses or telescope reflectors. It is doubtful if such precise construction would be justified, and in fact, as much educational value could probably be gained from a relatively crude model. It is suggested that the techniques for making relief maps be used as a guide if such construction is undertaken.

Transpositions and the Calculation of Inductance from Geometric Mean Distances

W. B. BOAST
MEMBER AIEE

Synopsis: The calculation of the inductance of power transmission lines by the method of geometric mean distances is discussed in most transmission line textbooks. The assumption is usually made therein that the single-phase case for which the return currents are established uniformly equal to $-I/n$ in the return n conductors may be expanded automatically to encompass also the transposed 3-phase case even though the return currents of the other two phases obviously do not satisfy the $-I/n$ condition. This paper demonstrates with mathematical rigour that the inductance per phase can be calculated by the geometric-mean-distance method, and further, it shows the necessary and sufficient conditions for the system of transpositions that must be satisfied for the general 3-phase case. For special 3-phase systems, possessing symmetry among certain spacing distances some of these transpositions, however, may then be unnecessary.

THE total inductance of a circuit expressed in henrys is defined as the derivative of the meter-kilogram-second flux linkages with respect to the total current of the circuit in amperes. In transmission line systems the components of flux linkage are linearly proportional to the various currents acting in the system if there are no magnetic materials present and this linear type of system is herein considered. The inductance then becomes the flux linkages per ampere.

The general expression for the flux linkages per unit of circuit length for one conductor due to N parallel solid cylindrical conductors is

$$\lambda_1 = 2\times 10^{-7}\left[I_1\left(\frac{1}{4}+\ln\frac{1}{r_1}\right)+\sum_{k=2}^{k=N} I_k \ln\frac{1}{D_{1k}}\right] \quad (1)$$

where

λ_1 = meter-kilogram-second flux linkages per meter of conductor 1
I_1 = current of the number 1 conductor in amperes
I_k = current of each of the other conductors in amperes and designated in the same direction as is I_1
r_1 = radius of conductor 1, in any unit of length
D_{1k} = distances from the center of conductor 1 to the center of the respective conductors, measured in the same unit of length as r

The derivation of this or similar expressions may be found in several textbooks[1-6] dealing with magnetic fields or with transmission lines.

The vector or scalor nature of λ_1 is determined by the similar nature of the currents. If the currents are the instantaneous (scalar) currents existing in the conductors at an instant of time, the flux linkage is likewise the instantaneous (scalar) linkage at that same instant of time. However, if the currents are steady-state harmonic currents with a vector designation with respect to some reference, the flux linkage is likewise a vector flux linkage with the same reference; and as such may be converted to a vector voltage drop by multiplying by $j2\pi f$. This latter designation is quite convenient in handling some untransposed line problems which cannot be treated rigorously by the method of geometric mean distances and the concept of a real self-inductance.

Linkage Relationships for $N+n$ Conductors

Figure 1 represents the cross-sectional view of two or more parallel nonmagnetic cylindrical conductors. The conductors carrying the total current $+I$ (those on the left in the figure) will be numbered from 1 to N and each carries a current of $+I/N$. Only two areas are shown in the figure, that is, N is equal to 2.

The conductor or conductors carrying the total return current will be designated by letters from a to n. In the case of polyphase circuits this return current will flow in all of the conductors of all the other phases where attention has already been directed to a particular phase in the designation of the N parts. Only two conductors are shown in the figure, that is n is equal to b (or 2). No restriction is made that each conductor carries a current of $-I/n$.

If all the $N+n$ currents of the system are designated in the same direction, the linkages about element 1 per meter are

$$\lambda_1 = 2\times 10^{-7}\left[\frac{I}{N}\left(\frac{1}{4}+\ln\frac{1}{r_1}+\sum_{k=2}^{k=N}\ln\frac{1}{D_{1k}}\right)+\sum_{k=a}^{k=n} I_k \ln\frac{1}{D_{1k}}\right] \quad (2)$$

The distances D_{1k} for $k=2$ to N are the distances between centers of elements of the parts of the conductor or conductors carrying the current $+I$ and for $k=a$ to n the distances are between elements of the going and return currents.

Similar expressions may be written for the linkages about elements 2, 3, 4, —to N. The sum of all the linkages about all of the N elements will give the linkages about the entire conductor or conductors carrying the total current $+I$ but referred to a current of I/N. A

Paper 50-246, recommended by the AIEE Basic Sciences, Transmission and Distribution Committees and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23-27, 1950. Manuscript submitted March 8, 1950; made available for printing August 25, 1950.

W. B. Boast is Professor of Electrical Engineering at Iowa State College, Ames, Iowa.

linkage has been defined in a manner that makes it depend upon the current to which it is referred, and one linkage about one of N equal elements of a conductor system should contribute only $1/N$ of a linkage with respect to the entire conductor system. Consequently the sum of the linkages about elements 1 to N must be divided by N to preserve the total conductor linkages with respect to the entire conductor system.

Then

$$\lambda=\frac{1}{N}\sum_{k=1}^{k=N}\lambda_k$$

$$=\frac{2\times10^{-7}I}{N^2}\left[\frac{1}{4}+\ln\frac{1}{r_1}+\sum_{k=2}^{k=N}\ln\frac{1}{D_{1k}}\right.$$

$$+\frac{1}{4}+\ln\frac{1}{D_{21}}+\ln\frac{1}{r_2}+\sum_{k=1}^{k=N}\ln\frac{1}{D_{2k}}$$

$$+\frac{1}{4}+\sum_{k=1}^{k=2}\ln\frac{1}{D_{3k}}+\ln\frac{1}{r_3}+\sum_{k=4}^{k=N}\ln\frac{1}{D_{3k}}$$

$$+\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots$$

$$\left.+\frac{1}{4}+\sum_{k=1}^{k=N-1}\ln\frac{1}{D_{Nk}}+\ln\frac{1}{r_N}\right]$$

$$+\frac{2\times10^{-7}}{N}\left[\sum_{k=a}^{k=n}I_k\ln\frac{1}{D_{1k}}+\right.$$

$$\sum_{k=a}^{k=n}I_k\ln\frac{1}{D_{2k}}+\ldots+$$

$$\left.\sum_{k=a}^{k=n}I_k\ln\frac{1}{D_{Nk}}\right] \quad (3)$$

Combining like terms in the first group gives

$$\lambda=\frac{2\times10^{-7}I}{N^2}\left[\frac{N}{4}+\sum_{k=1}^{k=N}\ln\frac{1}{r_k}+\right.$$

$$2\sum_{k=2}^{k=N}\ln\frac{1}{D_{1k}}+2\sum_{k=3}^{k=N}\ln\frac{1}{D_{2k}}$$

$$+\ldots+2\sum_{k=N-1}^{k=N}\ln\frac{1}{D_{(N-2)k}}+$$

$$\left.2\ln\frac{1}{D_{(N-1)N}}\right]+\frac{2\times10^{-7}}{N}\times$$

$$\left[\sum_{k=a}^{k=n}I_k\left(\frac{1}{D_{1k}}+\ln\frac{1}{D_{2k}}+\ldots+\ln\frac{1}{D_{Nk}}\right)\right] \quad (3A)$$

Several approaches to this equation can be made. Several slightly different approaches may be found in the transmission textbooks mentioned previously.[2,3,4,5] However, in no case is the result rigorously proved for polyphase systems inasmuch as all approaches assume that each of the n currents of the return system are equal.

Single-Phase Systems

Although the principal purpose of this discussion is a consideration of the necessary and sufficient conditions for transpositions in the polyphase case, the results for the single-phase case are included here for completeness. If the mathematical restriction that each current in the n group is equal to $-I/n$ is applied to equation 3A, then

$$\lambda=\frac{2\times10^{-7}I}{N^2}\left[\frac{N}{4}+\sum_{k=1}^{k=N}\ln\frac{1}{r_k}+\right.$$

$$2\sum_{k=2}^{k=N}\ln\frac{1}{D_{1k}}+2\sum_{k=3}^{k=N}\ln\frac{1}{D_{2k}}$$

$$+\ldots+2\sum_{k=N-1}^{k=N}\ln\frac{1}{D_{(N-2)k}}+$$

$$\left.2\ln\frac{1}{D_{(N-1)N}}\right]$$

$$-\frac{2\times10^{-7}I}{nN}\left[\sum_{k=a}^{k=n}\left(\ln\frac{1}{D_{1k}}+\right.\right.$$

$$\left.\left.\ln\frac{1}{D_{2k}}+\ldots+\ln\frac{1}{D_{Nk}}\right)\right] \quad (4)$$

Combining the various logarithmic terms and writing out the summations, which now become products, give

$$\lambda=2\times10^{-7}I\left[\frac{1}{4N}+\right.$$

$$\left.\ln\frac{\sqrt[nN]{[D_{1a}D_{1b}\ldots D_{1n}][D_{2a}D_{2b}\ldots D_{2n}]\ldots\ldots[D_{Na}D_{Nb}\ldots D_{Nn}]}}{N^2\sqrt{[r_1r_2\ldots r_N][D_{12}D_{13}\ldots D_{1N}]^2[D_{23}D_{24}\ldots D_{2N}]^2\ldots[D_{(N-2)(N-1)}D_{(N-1)N}]^2}}\right] \quad (5)$$

The $1/4\ N$ term is derived from the internal portion of the linkages of the system of N conductors and hence is associated with the denominator term involving the self dimensions.

Inasmuch as

Figure 1. A system of $N+n$ conductors

$$\frac{1}{4N}=\ln\frac{1}{N^2\sqrt{e^{-N/4}}} \quad (6)$$

equation 5 may be rewritten as

$$\lambda=2\times10^{-7}I\ln\frac{\sqrt[nN]{[D_{1a}D_{1b}\ldots D_{1n}][D_{2a}D_{2b}\ldots D_{2n}]\ldots\ldots[D_{Na}D_{Nb}\ldots D_{Nn}]}}{N^2\sqrt{e^{-N/4}[r_1r_2\ldots r_N][D_{12}D_{13}\ldots D_{1N}]^2[D_{23}D_{24}\ldots D_{2N}]^2\ldots[D_{(N-2)(N-1)}D_{(N-1)N}]^2[D_{(N-2)N}]^2[D_{(N-1)N}]^2}} \quad (6A)$$

The numerator of the logarithm involves all the mutual distances between elements of the two sides of the single-phase system and is defined as the *mutual geometric mean distance* between the total current $+I$ and its return. The symbol D_m is commonly employed as an abbreviation.

The denominator of the logarithm involves the distances among the N elements of the total current $+I$ and is defined as the *self-geometric mean distance* of the N group of conductors. The symbol D_{SN} is commonly employed as an abbreviation.

The self-inductance per unit of circuit length of the N group of conductors is $d\lambda/dI$, or with no nonlinear magnetic materials present, simply λ/I, and

$$L_N=2\times10^{-7}\ln\frac{D_m}{D_{SN}}\ \text{henrys/meter} \quad (7)$$

The self-inductance of the n group of conductors (the return) is obtained in the same manner by interchanging the n and the N. The mutual geometric mean distance is not changed by this procedure. If the symbol D_{Sn} is used for the self-geometric mean distance of the n group

$$L_n=2\times10^{-7}\ln\frac{D_m}{D_{Sn}}\ \text{henrys/meter} \quad (8)$$

Figure 2. A system of 3N conductors for N=2

The total inductance per unit of circuit length of the single-phase system is

$$L = L_N + L_n = 2\times10^{-7} \ln \frac{D_m^2}{D_{SN} D_{Sn}} \quad \text{henrys/meter} \tag{9}$$

Transpositions in Single-Phase Systems

The preceding relationships assumed that each current in the N group of conductors was the same, and also that each of the n currents of the return also were identical to each other.

Several conditions are necessary and sufficient in order that these equalities of currents exist. Each of the N conductors must possess the same resistance and also be so oriented with respect to the return and to each other that over the length of the line the induced voltage in each conductor is the same as in every other conductor of the N group. Similar conditions must apply to each of the n group.

Usually each of the N conductors of a system will be the same as every other of that group as regards configuration and materials. Likewise the n conductors will usually be the same within that group. Hence the only physical requirement of the line is that the necessary transpositions be effected unless symmetry of mutual dimensions has already established the sufficient conditions for balanced inductive effects.

The most general type of transposition, where the N conductors are assigned to N positions and likewise the n conductors are assigned to a different set of n positions and no interchange of conductors is permitted between these two group positions, requires Nn transposition sections.

Table I illustrates the schedule of positions needed for the general case where no symmetry exists among any parts. The original positions of conductors 1 and a are used for reference positions for other sections. Thus section $1b$ indicates that conductors of the N group have not moved but that b lies where a did in section $1a$, and the others in the n group have moved in a similar cyclic order.

Very often symmetry may obviate the need for many sections of transpositions which might otherwise be necessary.

The transpositions do not influence the calculations of the inductance in the single-phase case where the N-group and the n-group of conductors are each assigned to their own respective positions, but are necessary (except for symmetrical combinations) and sufficient for the use of I/N and I/n as common factors for the establishment of equation 4.

Polyphase Systems and Their Transpositions

A restricted type of polyphase system will be discussed, consisting of three phases, each of which contains N identical conductors. A general discussion for p phases each containing a different number of conductors is possible but becomes very involved and tedious in specifications. The use of an equal number of identical phase conductors is common in most multicircuit power transmission lines. Likewise 3-phase transmission lines are almost universal. For certain applications which may not be covered by this discussion with these restrictions, a solution for the particular case can be developed from the fundamental linkage equations perhaps as quickly as attempting to interpret a very involved derived result.

The n conductors of the return (where attention has been directed to one phase of N conductors) for the 3-phase system consists of $2N$ conductors. Rather than continue with this notation, a more direct system of symbols will be used. The letters of the alphabet will be used as phase designators (which is a common notation) and numbers will be used to indicate the conductor number of that phase. Thus conductor $b2$ indicates conductor number 2 of the b phase and conductor cN indicates the Nth conductor of the c phase. These double symbols will be used as subscripts for distance designations. Thus D_{b2-cN} indicates the distance from the center of conductor $b2$ to that of cN. Figure 2 illustrates a system for $N=2$.

The linkages per meter of the a phase, if the N currents of each phase are the same, are

$$\lambda = \frac{2\times10^{-7}}{N^2}\left\{ I_a\left[\frac{N}{4} + N\ln\frac{1}{r} + 2\sum_{k}^{k=N}\ln\frac{1}{D_{a1-ak}} + 2\sum_{k=2}^{k=N}\ln\frac{1}{D_{a2-ak}} + \ldots + 2\sum_{k=N-1}^{k=N}\ln\frac{1}{D_{a(N-1)-ak}} + 2\ln\frac{1}{D_{a(N-1)-aN}}\right] + \sum_{k=1}^{k=N} I_b\left(\ln\frac{1}{D_{a1-bk}} + \ln\frac{1}{D_{a2-bk}} + \ldots + \ln\frac{1}{D_{aN-bk}}\right) + I_c\left(\ln\frac{1}{D_{a1-ck}} + \ln\frac{1}{D_{a2-ck}} + \ldots + \ln\frac{1}{D_{aN-ak}}\right)\right\} \tag{10}$$

The equality of the N currents in the N identical conductors of each phase is desirable to maintain minimum losses for a fixed amount of conductor material and total current. A cyclic order of simultaneous transpositions within each group of phase conductors is both necessary and sufficient to accomplish this balance for the general case where no symmetry exists.

Furthermore, balanced inductive voltage drops are desirable among phases under balanced current conditions so that each phase may possess the same voltage regulation as every other phase. Transpositions among phases are necessary and sufficient to accomplish this balance for the general case where no symmetry exists.

Table II illustrates the schedule of positions needed for the general case of no symmetry. The reference system for transposition sections follows the same plan as was used in the single-phase case. The linkage equation 10 is the same for section $a1$, $a2$, $a3$, ... aN since interchanging equal components of phase currents in the assigned phase positions does not influence this equation.

However, the linkages of phase a for the transposition sections of the b group and also of the c group are different and must be considered. If the linkages of equation 10 are called λ_{ak}, then λ_{bk} will mean the linkages of phase a when phase b conductors have been transferred to the original phase a positions. If the distance notation for the first (ak) section is used throughout, then

$$\lambda_{bk} = \frac{2\times10^{-7}}{N^2}\left\{ I_a\left[\frac{N}{4} + N\ln\frac{1}{r} + 2\sum_{k=2}^{k=N}\ln\frac{1}{D_{a1-ak}} + 2\sum_{k=3}^{k=N}\ln\frac{1}{D_{a2-ak}} + \ldots + 2\sum_{k=N-1}^{k=N}\ln\frac{1}{D_{a1-ak}} + 2\ln\frac{1}{D_{a(n-1)-an}}\right] + \sum_{k=1}^{k=N}\left[I_b\left(\ln\frac{1}{D_{a1-ak}} + \ln\frac{1}{D_{a2-ak}} + \ldots + \ln\frac{1}{D_{aN-ak}}\right) + I_c\left(\ln\frac{1}{D_{a1-bk}} + \ln\frac{1}{D_{a2-bk}} + \ldots + \ln\frac{1}{D_{aN-bk}}\right)\right]\right\} \tag{11}$$

Table I. Single-phase Transposition Schedule

Transposition Section	N-Group Positions					n-Group Positions			
1a	1	2	...	N		a	b	...	n
1b	1	2	...	N		b	c	...	a
⋮	⋮	⋮	⋮			⋮	⋮	⋮	
1n	1	2	...	N		n	a	...	(n−1)
2a	2	3	...	1		a	b	...	n
2b	2	3	...	1		b	c	...	a
⋮	⋮	⋮	⋮			⋮	⋮	⋮	
2n	2	3	...	1		n	a	...	(n−1)
⋮	⋮	⋮	⋮			⋮	⋮	⋮	
Na	N	1	...	(N−1)		a	b	...	n
Nb	N	1	...	(N−1)		b	c	...	a
⋮	⋮	⋮	⋮			⋮	⋮	⋮	
Nn	N	1	...	(N−1)		n	a	...	(n−1)

and

$$\lambda_{ck}=\frac{2\times10^{-7}}{N^2}\left\{I_a\left[\frac{N}{4}+N\ln\frac{1}{r}+\right.\right.$$

$$2\sum_{k=2}^{k=N}\ln\frac{1}{D_{b1-bk}}+2\sum_{k=1}^{k=N}\ln\frac{1}{D_{b2-bk}}$$

$$+\ldots+2\sum_{k=N-1}^{k=N}\ln\frac{1}{D_{b(N-2)-bk}}+$$

$$\left.2\ln\frac{1}{D_{b(N-1)-bN}}\right]$$

$$+\sum_{k=1}^{k=N}\left[I_b\left(\ln\frac{1}{D_{b1-ck}}+\ln\frac{1}{D_{b2-ck}}+\right.\right.$$

$$\left.\ldots+\ln\frac{1}{D_{bN-ck}}\right)+I_c\left(\ln\frac{1}{D_{b1-ak}}+\right.$$

$$\left.\left.\left.\ln\frac{1}{D_{b2-ak}}+\ldots+\ln\frac{1}{D_{bN-ak}}\right)\right]\right\}\quad(12)$$

The average linkage per meter of the transposed system then will be the sum of the three equations 10, 11, and 12 divided by three. This yields the equation

$$\text{Average }\lambda\text{ of phase }a=\frac{2\times10^{-7}}{3N^2}\times$$

$$\left\{I_a\left[\frac{3N}{4}+3N\ln\frac{1}{r}+2\sum_{k=2}^{k=N}\times\right.\right.$$

$$\left(\ln\frac{1}{D_{a1-ak}}+\ln\frac{1}{D_{b1-bk}}+\ln\frac{1}{D_{c1-ck}}\right)+$$

$$2\sum_{k=3}^{k=N}\left(\ln\frac{1}{D_{a2-ak}}+\ln\frac{1}{D_{b2-bk}}\ln\frac{1}{D_{c2-ck}}\right)$$

$$+\ldots\ldots\ldots\ldots$$

$$+2\sum_{k=N-1}^{k=N}\left(\ln\frac{1}{D_{a(N-2)-ak}}+\right.$$

$$\left.\ln\frac{1}{D_{b(N-2)-bk}}+\ln\frac{1}{D_{c(N-2)-ck}}\right)+$$

Table II. Three-Phase Transposition Schedule

Transposition Section	Conductor Pattern							
a1	a1	a2	...	aN	b1	b2	...	bN	c1	c2	...	cN
a2	a2	a3	...	a1	b2	b3	...	b1	c2	c3	...	c1
⋮	⋮	⋮	⋮		⋮	⋮	⋮		⋮	⋮	⋮	
aN	aN	a1	...	a(N−1)	bN	b1	...	b(N−1)	cN	c1	...	c(N−1)
b1	b1	b2	...	bN	c1	c2	...	cN	a1	a2	...	aN
b2	b2	b3	...	b1	c2	c3	...	c1	a2	a3	...	a1
⋮	⋮	⋮	⋮		⋮	⋮	⋮		⋮	⋮	⋮	
bN	bN	b1	...	b(N−1)	cN	c1	...	c(N−1)	aN	a1	...	a(N−1)
c1	c1	c2	...	cN	a1	a2	...	aN	b1	b2	...	bN
c2	c2	c3	...	c1	a2	a3	...	a1	b2	b3	...	b1
⋮	⋮	⋮	⋮		⋮	⋮	⋮		⋮	⋮	⋮	
cN	cN	c1	...	c(N−1)	aN	a1	...	a(N−1)	bN	b1	...	b(N−1)

$$2\left(\ln\frac{1}{D_{a(N-1)-an}}+\ln\frac{1}{D_{b(N-1)-bn}}+\right.$$

$$\left.\ln\frac{1}{D_{c(N-1)-cN}}\right)\Bigg]+\sum_{k=1}^{k=N}\left[I_b\left(\ln\frac{1}{D_{a1-bk}}+\right.\right.$$

$$\ln\frac{1}{D_{a2-bk}}+\ldots+\ln\frac{1}{D_{aN-bk}}+$$

$$\ln\frac{1}{D_{b1-ck}}+\ln\frac{1}{D_{b2-ck}}+\ldots+\ln\frac{1}{D_{bN-ck}}$$

$$+\ln\frac{1}{D_{c1-ak}}+\ln\frac{1}{D_{c2-ak}}+\ldots+$$

$$\left.\ln\frac{1}{D_{cN-ak}}\right)+I_c\left(\ln\frac{1}{D_{a1-ck}}+\ln\frac{1}{D_{a2-ck}}\right.$$

$$+\ldots+\ln\frac{1}{D_{aN-ck}}+\ln\frac{1}{D_{b1-ak}}+$$

$$\ln\frac{1}{D_{b2-ak}}+\ldots+\ln\frac{1}{D_{bN-ak}}+\ln\frac{1}{D_{c1-bk}}+$$

$$\left.\left.\ln\frac{1}{D_{c2-bk}}+\ln\frac{1}{D_{cN-bk}}\right)\right]\Bigg\}\quad(13)$$

The multipliers upon the I_b and the I_c are identical. Inasmuch as I_b+I_c is equal to $-I_a$, equation 13 may be rewritten (following similar reasoning regarding the (1/4) N term as was explained in the single-phase case) as

$$\text{Average }\lambda\text{ of phase }a=2\times10^{-7}I_a\times$$

$$\ln\frac{\dfrac{3N^2\left|\begin{array}{l}[D_{a1-b1}D_{a1-b2}\ldots D_{a1-bN}]\\[D_{a2-b1}D_{a2-b2}\ldots D_{a2-bN}]\\\ldots\ldots[D_{aN-b1}D_{aN-b2}\ldots D_{aN-bN}]\\[D_{b1-c1}D_{b1-c2}\ldots D_{b1-cN}]\\[D_{b2-c1}D_{b2-c2}\ldots D_{b2-cN}]\\\ldots\ldots[D_{bN-c1}D_{bN-c2}\ldots D_{bN-cN}]\\[D_{c1-a1}D_{c1-a2}\ldots D_{c1-aN}]\\[D_{c2-a1}D_{c2-a2}\ldots D_{c2-aN}]\\\ldots\ldots[D_{cN-a1}D_{cN-a2}\ldots D_{cN-aN}]\end{array}\right|}{\sqrt{\begin{array}{l}3N^2e^{-3N/4\mu_r}[D_{a1-a1}D_{a1-a2}\ldots D_{a1-aN}]^2\\[D_{b1-b1}D_{b1-b2}\ldots D_{b1-bN}]^2\\[D_{c1-c1}D_{c1-c2}\ldots D_{c1-cN}]^2\\[D_{a2-a1}D_{a2-a}\ldots D_{a2-aN}]^2\\[D_{b2-b1}D_{b2-b1}\ldots D_{b2-bN}]^2\\[D_{c2-c1}D_{c2-c1}\ldots D_{c2-cN}]^2\\\ldots\ldots[D_{a(N-2)-a(N-1)}D_{a(N-2)-aN}]^2\\[D_{b(N-2)-b(N-1)}D_{b(N-2)-bN}]^2\\[D_{c(N-2)-c(N-1)}D_{c(N-2)-cN}]^2\\[D_{(aN-1)-cN}]^2[D_{b(N-1)-bN}]^2\\[D_{c(N-1-cN}]^2\end{array}}}\quad(14)$$

The numerator of the logarithm involves all of the mutual distances taken in all combinations of the transposed line and is defined as the *mutual geometric mean distance* between the current I_a and its return. The same symbol D_m may be used as for the single-phase case but it represents the equivalent value for the transposed system of phase positions.

The denominator of the logarithm involves the various combinations of distances among the conductors of the same phase and is defined as the *self-geometric mean distance* of the phase conductors. The symbol D_s may be employed as an abbreviation.

Attention has been directed in the derivation of equation 14 at phase a of the polyphase system. The complete system of transpositions, however, has made each phase equivalent to every other in so far as geometric conditions are concerned. Hence D_m and D_s are the same for phases b and c as for phase a. Therefore no phase subscripts are used on the symbols. The average inductance per unit of circuit length of any phase of the transposed system then is

$$L=2\times10^{-7}\ln\frac{D_m}{D_s}\text{ henrys/meter}\quad(15)$$

Dial Telephone Central Office Buildings for Small Communities

F. D. REESE
ASSOCIATE AIEE

E. C. ROYS
NONMEMBER AIEE

BECAUSE of increasing costs, the design of dial telephone central office buildings for small communities is being scrutinized closely by most telephone operating companies, with the object of specifying the most economical type of construction consistent with the rather special requirements. In examining this problem, it is necessary first to review the requirements, after which the elements of the problem can be identified, and proposed solutions for the several elements can be discussed separately. The general building design features are determined chiefly by the type of community and the climate, while the detailed design is governed by the housing requirements of the equipment. These factors are examined in detail and solutions to the various problems encountered are discussed in some detail.

Type of Central Office Under Consideration

The type of central office under consideration is that generally referred to in the industry as a community dial office. This is defined as a small telephone central office arranged to complete calls within a community by machine switching, and having facilities to enable users to pass all calls, such as toll calls or service calls, requiring handling by operators to a nearby central office having operators in attendance.

Paper 50-248, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 25, 1950; made available for printing August 31, 1950.

F. D. Reese and E. C. Roys are both with the Pennsylvania Telephone Corporation, Erie, Pa.

General Building Design Features

The considerations which control the general design are:

Range of Sizes

The maximum size required, while not inflexibly fixed, may be taken as that required for a machine switching apparatus having a capacity of 1,000 subscriber lines. The floor dimensions usually employed fall into the size divisions given in Table I which are for a single story building with no basement.

The maximum sizes indicated provide additional floor space where required for trunk terminations, carrier terminals or telephone repeaters, and in general are for offices having a greater than average number of toll or trunk lines to adjacent offices.

Table I

Subscriber Lines Accommodated	Floor Dimensions Maximum, Feet	Minimum, Feet
100	12 by 14	8 by 12
200	14 by 18	12 by 14
400	16 by 20	14 by 18
600	18 by 22	18 by 18
1,000	25 by 28	25 by 25

Location

The general design will be influenced by such factors as the type of community (whether rural or suburban); the prominence of the site in the community (whether on a main street or on a side street or alley); and the climatic conditions anticipated. The exact location of the site within the community will be determined by reference to the ultimate center of wire distribution, with consideration given to avoiding flood or fire hazards, or excessive vibration from trains or heavy machinery. Since the machine switching equipment will not require an attendant, all features of the building should be so designed as to permit satisfactory nonattended operation.

Consideration of these factors may indicate the need for inclusion in the general design of certain features, even though these add to the cost, such as:

1. Architectural decorative treatment or styling in harmony with neighboring structures, where a prominent site is chosen. Figure 1 illustrates such treatment.

2. A roof designed to support heavy snow loading, or to shed snow where winters are severe.

3. Fully fireproof construction, such as solid masonry, if hazard of fire cannot be avoided. Note concrete block walls, metal covered door and concrete base of the building illustrated in Figure 2.

4. Vibration-proof construction, such as a reinforced concrete floor slab if excessive vibration is foreseen.

Figure 1. Mayville, N. Y. central office

Figure 2. Jourdanton, Tex. central office

The control of cost through a choice of a less expensive design, such as frame construction, or through the elimination of architectural decorative effects, is therefore limited in certain instances.

Special Building Design Features

There should be considered as a basis for the detailed design those factors having an influence on the operation of the equipment to be housed. A discussion of these factors follows:

Resistance to Fire

Having in mind protection of the communication service, full consideration should be given fire risks. It has already been indicated that where the fire hazard is excessive, full fireproof construction should be considered. At locations where the risk of fire is a normal one, such as might be offered by a grass fire on the site, or by windborne sparks from a more remote fire, the exterior siding and roof covering should be of fire resistant material such as metal, asbestos siding or asphalt shingles.

Floor Loading

The load which will be imposed on the floor structure by the telephone equipment must be taken into account. Floor load varies from 125 to 150 pounds per square foot, depending on the type of equipment to be installed. The usual floor consists of a 5-inch slab of reinforced concrete which is amply strong and ordinarily not susceptible to vibration.

Figure 3. Brookings, Oreg. central office

Temperature Control

Insulation will be required in the ceiling or under the roof to prevent inside temperatures rising excessively in summer with resultant damage to potted apparatus or variation in relay or switch adjustments due to the unequal expansion of dissimilar metals. For example, in a building located in the Sacramento Valley in California, an interior temperature of 128 degrees Fahrenheit has been recorded. In buildings which are not to be heated, no wall or floor insulation is necessary, except in the case of buildings constructed of metal which require insulation to prevent condensation of moisture on the metal inside surfaces. Insulating board such as Celotex or asbestos sheets is the usual choice. If a fibrous material such as Celotex is used, it should be treated with a sealer on the inside surfaces to avoid any possibility of wear releasing fibrous particles which would interfere with the operation of the equipment by fouling the electrical contacts of relays or switches.

Heat is required in nonattended dial offices principally to provide some degree of comfort for maintenance personnel during short periodic visits made for the purpose of inspecting or routining the equipment. An exception would be the case of an office located in an extremely cold climate. Here it may be necessary to provide heaters, usually electric, arranged to prevent the temperature dropping to a very low level, with resultant possibility of variation in relay or switch adjustments through unequal contraction of dissimilar metals in spring assemblies.

Some use has been made in buildings of up to 400 lines capacity of portable electric heaters comprised of a 2- or 3-kw heating element with an associated blower. These are carried from office to office by the maintenance personnel and used either as spot heaters directed toward the piece of equipment being routined, or as a unit heater placed in operation long enough to warm the building sufficiently to permit work to proceed. They seem to be unsatisfactory to the maintenance people when so used, because they are not adequate to provide quickly any considerable temperature increase and because the floors are not warmed. Further, intermittent heating, with consequent variation of the dew point of the air within the building, makes control of moisture condensation difficult. In cases where heating is proposed, usually it is advisable to consider fixed heater installations.

Figure 4. Seven Corners, N. D. central office

The building being nonattended, automatic heater operation under control of a thermostat is essential. An electric heater, oil burner or gas-fired heater meets this requirement. Because of the higher cost of operating the conventional electric convection heater, oil- or gas-fired heaters are quite frequently used, but these offer serious disadvantages, the principal ones being:

1. Small oil heaters, which ordinarily are of the wick or pot type, give rise to fumes which are an explosion hazard, unless very well maintained. In addition, there is a possibility of a backfire (caused by faulty draft) spreading soot which would foul the equipment with resultant disruption of service.

2. Gas-fired heaters, while cleaner than oil heaters, may present a greater explosion hazard. In a nonattended building, there would be no opportunity for detection of a gas leak. Any slight leak might result in the accumulation of gas sufficient to form an explosive mixture with the air.

3. The minimum length of flue required to insure good draft is seldom if ever attained in these small buildings. Since one of the products of combustion is water vapor, any deficiency in draft might result in introducing moisture into the building. It therefore appears that neither gas nor oil is entirely satisfactory as a fuel.

Fixed electric heaters, because of the high cost of operation, are used more at present for the prevention of equipment trouble due to very low temperatures, than for heating sufficiently to contribute to the efficiency of the maintenance personnel. For example, in North Dakota,

Figure 5. Cooperstown, Pa. central office

the Northwestern Bell Telephone Company uses electric heaters of three kw capacity to prevent the temperature dropping below 10 to 15 degrees above 0 degrees Fahrenheit. The Northern Ohio Telephone Company uses similar heaters to hold the temperature between 15 and 20 degrees Fahrenheit.

A possible solution to the heating problem is seen in the electric radiant heaters now available. Preliminary investigation of one type seems to indicate considerable promise of successful operation at a reasonable cost. The type under investigation is comprised of panels arranged for mounting on the ceiling, each containing a layer of electrically conductive rubber sandwiched between layers of paper impregnated with phenolic resin. The principle involved is that heat is radiated from the ceiling panels to the walls, floor and other solid objects, including the equipment frames and cabinets, without directly heating the air. The effect noticed by personnel is a sensation of warmth which results from a reduction in the rate of heat transfer from body surfaces. This effect is in a considerable degree independent of the air temperature.

Estimates of annual operating costs have been prepared by the manufacturer for average Chicago weather. These estimates are based on a 400-line building of concrete block construction built on a 5-inch concrete slab and having a frame roof covered with asphalt shingles. The proposal is to maintain a minimum temperature of 40 degrees Fahrenheit during the winter. With four inches of insulation in the ceiling, but without wall or floor insulation, the annual power consumption is estimated at 1,480 kilowatt hours representing a cost of $44.40 annually at a power rate of three cents per kilowatt hour. Adding two inches of insulation to the walls and between the floor slab and its footings would reduce the power consumed to 1,030 kilowatt hours representing a cost of $30.90 annually. These costs will be increased materially if workmen raise the thermostat setting during periods when they occupy the building. The installed cost of the panels required to meet these conditions will be less than $300.

Figure 6. Vintondale, Pa. central office

Control of Moisture

The effect of moisture condensation or absorption on central office equipment is to lower the insulation resistance of wiring or cables, and of apparatus assembled on spacer blocks of insulating materials. The result can readily be failure of the functioning of the apparatus affected. Any absorption of moisture in the insulating covering of conductors in cables may result in a virtual short circuit. The cables carry 48-volt d-c potentials, and under such a condition it is possible that a severe electrical burn may occur with consequent interruption of service and serious damage to the equipment. Means of preventing accumulation of moisture within the building are therefore of great importance.

Seepage of moisture through concrete floors can be eliminated either by supporting the floor slab on footings above the ground level, or by pouring the concrete on a waterproof membrane such as impregnated building paper laid on a fill of cinders or gravel. Where an extremely dry soil is encountered, such as well-drained pure sand, no particular precaution may be necessary.

Condensation of moisture within the building results from the exposure of cold surfaces to warmer air which has a high relative humidity, or from admitting warm humid air to the building which will later become cooled below the dew point. Probably because of varying climates in different sections of the country, there is a diversity of opinion among engineers as to the measures necessary to control condensation.

Ventilation seems to be effective at some locations, but less so at others. The theory applied where ventilation is employed seems to be that vents should have movable louvers which can be opened during warm weather, permitting equalization of the temperature of the air within the building with the temperature of the air outside. However, many engineers believe that hermetic sealing during humid weather is more effective, on the theory that the less air is admitted, the less moisture may accumulate. Ventilation does offer one disadvantage, in that dust may be introduced into the building, with resultant possible fouling of relay or switch contacts. This may be partially overcome by locating the vents on the same wall rather than on opposite walls. The Telephone Service Company of Ohio provides vents equipped with movable louvers which are normally open but close under control of a thermostat when the temperature falls to 32 degrees Fahrenheit inside the building.

Electric dehumidifying equipment can be applied to remove moisture. Such equipment removes moisture from the air by cooling at the point of intake. When operated under control of a humidistat, these devices are efficient, but because first cost and operating cost would be fairly high, their employment would be limited to locations, such as tropical locations, where long periods of very high humidity might be anticipated. Another practical disadvantage is that during hot weather, employees may be influenced to seek relief from the heat through unnecessary visits to the building so equipped.

At humid locations, chemical dehydrators, employing a hygroscopic compound, would be effective. However, these usually result in the accumulation of a highly corrosive residue, raising a problem of disposal, and are not widely recommended.

The covering of interior surfaces with an insulating material will be found necessary in the case of buildings sheathed with steel, or built of ordinary glazed building tile. However, some areas report the successful use of hollow tile for wall construction, where the tiles are so formed as to provide drainage within the wall to a drainage vent at or near the foundation, and where a choice of interior glazes can be made which will eliminate condensation on the interior wall surfaces.

Where heaters are provided, they may be turned on during extremely humid weather so as to raise the air temperature and consequently the dew point, thus preventing condensation of moisture.

Other Special Features

There are certain other features which, while not requiring detailed discussion, should be mentioned. These are:

1. The door should be of sufficient size to

Figure 7. Waldo, Ohio central office

provide for entrance of the switching equipment to be housed.

2. Fixtures requiring plumbing should be avoided because of the cost of providing water and waste connections. Further, the introduction of water piping would make it necessary to heat sufficiently to avoid freezing, at the least.

3. While the telephone storage batteries ordinarily have a considerable reserve capacity, it might be necessary, in case of a protracted failure of the commercial power supply, to introduce a portable emergency engine-generator set. At slight cost, an electric receptacle can be provided to facilitate plugging in such portable equipment. The receptacle should preferably be provided for an alternating voltage source, since a-c operated equipment, such as telephone repeaters or carrier terminals, may be in service.

4. To minimize interruptions on the a-c circuits supplying battery chargers, such circuits should be fused separately from circuits provided for lighting or convenience outlets.

Typical Building Designs

From the foregoing it is apparent that no one design will be applicable to all locations and all conditions. Instead, various companies operating in various parts of the country have developed designs which best meet the conditions encountered locally.

For example, the West Coast Telephone Company, having low first cost and portability in view, employs a wood frame building covered with asbestos cement shingles. In areas where heavy snow is expected, a hip roof of frame construction, covered with asbestos or asphalt shingles is used. In other areas a flat roof built up of roofing felt is used. A concrete floor slab provides a foundation. In some cases the building is constructed with an additional wood floor which sets on the concrete slab. This company has on occasion moved a building, complete with the equipment, a distance of 50 miles, at a reported cost, including the new concrete foundation, of $400. Figure 3 illustrates one of these frame buildings.

The Illinois Commercial Telephone Company constructs buildings of glazed hollow tile on a reinforced concrete floor slab. The slab is raised above the ground level to insure a dry floor. The roof is of frame construction and covered with asbestos or asphalt shingles. A ceiling of sheet asbestos is provided. There is no provision for heating. The same building design is used by Commonwealth Telephone Company in Wisconsin.[7]

The Northwestern Bell Telephone Company employs frame construction in portable buildings for its operations in North Dakota. The walls are covered with asbestos shingles, and both walls and ceiling are insulated with four inches of rock wool, and covered inside with Transite sheets. The wood floor is insulated with eight inches of rock wool. The roof is of frame construction, covered with asphalt shingles. The temperature is held to a minimum of 10 to 15 degrees Fahrenheit by a thermostatically controlled electric heater of the blower type. These buildings are assembled and the equipment installed at Fargo, N. D. and then transported to the site of operation where they are set on posts to raise them about one foot off the ground. When set, the soil on the site is treated chemically to prevent growth of brush or weeds, and a surrounding fill of crushed stone is put in to guard against brush fires. The building illustrated in Figure 4 was built in Fargo, N. D., the equipment installed and the completed structure was then moved to Seven Corners, N. D.

Pennsylvania Telephone Corporation constructs masonry buildings on a reinforced concrete slab, using a concrete block made of a lightweight aggregate waterproofed with Portland cement paint, with an asphalt shingle roof. Small glass block windows are installed to provide some natural light without risking condensation of moisture such as occurs with single glass panes. A ceiling of sound absorbent material provides insulation. Electric receptacles are provided for portable electric heaters. In rural communities, the exterior walls are given a waterproof cement finish. In suburban communities, brick veneer is added to improve the appearance of the exterior. Ventilation is provided for by installing two small openings in one wall, with movable copper louvers, see Figures 5 and 6.

A similar building of the Ohio Associated Telephone Company is shown in Figure 7.

The San Joaquin Associated Telephone Company employs concrete framing in a brick building set on a 4-inch concrete slab. Glass block windows are placed in two walls to give some natural lighting. The roof is of frame and asbestos shingle construction. A plaster ceiling is employed and the attic space is vented by a rotary wind motor ventilator. The attic is vented into the room below, which in turn is vented through fixed louvers in the door.

General Telephone Corporation is investigating the feasibility of designing a prefabricated building which might either be assembled at the site, or transported there after assembly at a convenient central point. Preliminary investigation is under way of a metal building constructed of galvanized steel, aluminum, or stainless steel sheets stretched on a steel frame. The sheets would be stretched tight between the frame members by being wedged into supporting channels on all four sides. Either a flat or hip-type metal roof could be obtained. At least two inches of insulation would be required, and if electric heat were provided, at least twice that amount would be required to control heating cost. No ventilation would be required. This building, set on a concrete slab, would probably cost less than $1,200 in the 400-line size or well under one-half the cost of a masonry building of the same size.

Conclusion

Rising building costs are focusing attention on the need for an economical building design. An analysis of the cost of recently constructed masonry buildings has indicated to the authors that wood-frame construction should be specified for small offices in which limited operating revenues make control of plant investment a paramount consideration. For example, the bill of materials for a rather plain 200-line masonry building built this year was about $1,200, or about one-third the cost of the completed building. In the construction of this building, carpenters, masons, tile setters, electricians, bricklayers and truck drivers, with their helpers were necessary, and these craftsmen travelled daily to the site from neighboring cities. A low-cost building is not attainable under these conditions.

A building comprised of prefabricated metal or wood sections, which could be erected on the site by two or three workmen might offer a solution, but at this time, a suitable prefabricated design does not seem to be available.

A building of conventional wood-frame construction could in most cases be built in the small town by local craftsmen, and seems to offer the most promise for control of cost in such small communities. The recommendation of the authors for the design features of such a building are as follows:

1. The site should be on a secondary street rather than on a main street, to obviate the necessity for architectural ornamentation. A rear-lot site with alley access would be suitable if the neighboring structures do not offer fire hazards.

2. A reinforced concrete base poured over a waterproof membrane, laid on a gravel fill, should be specified to prevent moisture seeping through the floor.

3. The walls and roof should be covered

with asbestos shingles laid over 3/4-inch wood or composition sheathing to provide a degree of resistance to fire. Two inches of insulation in the form of strips laid between the studs and joists should be supplied. The interior should be finished with gypsum board or similar material nailed to the studs and ceiling joists thus avoiding the necessity for employing plasterers.

4. A wood floor of 3/4-inch plywood laid on wood joists and covered with linoleum or similar floor covering should be specified. Such a floor will be warmer than a concrete floor.

5. The space between ceiling and roof should be vented to prevent excessively high summer temperatures. No other ventilation is required. A gable rather than a hip roof may be specified for better ventilation. Storm water drains from the roof should be omitted to reduce costs.

6. A fire-resistant metal sheathed wood door should be specified. Metal weather stripping should be employed to eliminate entry of dust or rain.

7. Outlets should be provided for a thermostatically controlled electric heater of the blower type, and for a portable a-c engine-generator, for use in the event of a commercial power failure.

8. A 4-inch gravel fill should be placed around the building foundation for a distance of four feet, to prevent the walls being splashed by drainage from the roof and thereby stained. This fill should be sprayed to prevent growth of weeds.

9. In localities where termite infestation is prevalent, a sheet-metal shield should be installed along the upper edge of the foundation to prevent termite colonies reaching the wood floor or wall members.

No Discussion

General Aspects of Community Dial Office Equipment

ALBERT BURKETT
MEMBER AIEE

COMMUNITY dial central office equipment is used presently as central office equipment serving exchanges which vary in size from a few lines to several hundred lines. The equipment is usually located at a point some distance from traffic and plant department personnel and therefore must operate satisfactorily on an unattended basis, except for routine visits. The equipment should adequately provide all the necessary services required in its service area. It should be reasonable in first cost and low in maintenance. It should be compact in size so as to require a minimum building space, yet it should be easily accessible for maintenance. It is desirable that it be readily expandable to care for growth and for the addition of service features.

Community dial offices are telephone central offices of the dial-switching type that are designed particularly for small communities. They are distinguished by relatively small size, by a preponderance of multiparty lines, by equipment assemblies designed for quick installation at remote points, and by maintenance features to facilitate unattended operation with a high grade of service.

Low cost is an important objective in the design of community dial offices because they frequently serve sparsely settled areas where it is difficult to furnish adequate telephone service at reasonable costs. However, these offices are designed for providing all service features that may be desired by the customers at a reasonable cost.

Many community dial offices serve less than 100 subscriber lines. Other offices serve several hundred up to a thousand or more lines. Larger offices are generally considered outside of the community dial category, although their features may in many cases be essentially the same.

Service Features

General

The service features required for community dial offices vary from location to location, depending upon size of the office and its proximity to larger centers of population. However, these service features may be divided into two general classifications: those required in all offices; and those required for the particular installation in question.

Multiparty Lines

Provision must be made in all cases for serving lines on a multiparty basis and, in general, equipment capable of serving lines having eight or ten parties per line will be adequate. However, in certain areas it may be necessary that the equipment be arranged to handle lines serving up to 20 parties each. In smaller community dial offices individual, 2-party, and 4-party lines are handled as unfilled multiparty lines. Provision also may be made for handling a small group of lines on a consecutive line hunting basis. In addition to these lines which are arranged for flat rate service, it is usually necessary to serve coin stations. In a very large percentage of community dial offices these lines are served on a post payment coin basis, that is, deposit of coins after answer of the called party or upon request by the operator.

Uniform Audible Signals

In order that telephone users throughout the country may be able to dial calls in a uniform manner, it is necessary that any audible signals that they may encounter in making a call be uniform. The first of these audible signals which the user will encounter is dial tone, which tells him the equipment is ready for him to begin dialing. The time interval between removing the receiver from the telephone to application of dial tone should be as short as possible, to reduce to a minimum the probability of mutilated dialing. When the calling party has been connected to another line or to a trunk to an operator, he should receive an audible ringing indication to satisfy him that the called party or operator is being signaled. If the user encounters a busy condition, he should receive busy tone. Busy tone is a tone of the same fundamental frequency as dial tone but interrupted 60 times per minute. The length of the tone intervals and silent intervals being 0.5 second each.

Reverting Call Arrangements

Reverting call arrangements must be provided to enable stations on the same line to call each other. Where the exchange is equipped for bridged or divided code ringing, reverting calls may be made by the calling subscriber dialing the listed directory number of the desired station on his line. Upon completion of dialing busy tone will be returned. The calling subscriber then hangs up and the central office equipment tests to determine if the calling and called lines are the same. If so, the called code is rung. If the line is arranged for divided ringing, a reverting ring one half second in length should be rung on the opposite side of the line during each half of the ringing cycle. When ringing is tripped due to answer of the called party, the calling party lifts his receiver and the conversation may begin.

Paper 50-249, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23-27, 1950. Manuscript submitted July 25, 1950; made available for printing August 25, 1950.

Albert Burkett is with the Bell Telephone Laboratories, Inc., New York, N. Y.

In offices arranged to serve multiparty lines on a semiselective or full selective basis, reverting call selector circuits must be provided. These circuits are usually reached from a selector level of first selectors or their equivalent. In offices equipped with reverting call selectors, the calling party must dial an arbitrary number rather than the listed directory number to reach another station on his line. Otherwise the method of operation by the subscriber is essentially the same as for the directory number method.

Operator Office Trunks

Trunks for handling traffic to the operator office are reached by dialing "0" and are usually arranged for 2-way operation. In order that the trunks may be used with various types of outside plant facilities it is necessary that they be available for loop, composite, or simplex signaling operation. Since they are used in common by flat rate and coin subscribers, facilities are provided so that the operator may know when coin stations originate the calls, so she may request deposit of coins. This is usually done by applying a short spurt of dial tone at the time the operator answers. It is desirable that the arrangement should be such that the operator may check for this tone by pulling down the cord and replugging.

Under some conditions it may be desirable to route traffic from a community dial office through another community dial office used as a tandem center. For this arrangement, the trunks from a tandem center to the operator office are as previously described. The trunks between the end community dial office and the tandem point may be arranged for access to the operator office only, as shown in Figure 1, or for dual use as trunks to the operator office and as dial trunks for completing calls between subscribers at the end office and the tandem office, as shown in Figure 2. In either case, subscribers at the end community dial office should reach the operator by dialing a single digit "0". When the trunk is arranged to reach the operator office only, the dialing of the digit "0" causes the community dial office equipment to select a trunk to tandem. At the tandem office the trunk is automatically connected to one of the common groups of operator trunks, without the need of extra digits. If the trunk is arranged for traffic both to the operator and to the tandem office, the community dial office equipment selects the trunks to tandem when the subscriber dials "0" and then the trunk automatically sends a digit "1" to the tandem equipment. This digit causes a trunk to be selected to the operator office. If the trunk is used for a call terminating in the tandem office, a digit other than "0" is used to select the trunk, and then the regular listed directory number is dialed for completing the call.

In areas served by several community dial offices which reach the operator office through a tandem point, and where there is a toll charge for calls between offices, as shown in Figure 1, it is sometimes desirable to use dial-back type operator office trunks between the tandem office and the operator office. Dial back operator office trunks are trunks over which an operator may receive an incoming call from a community dial office and complete it by dialing back over the same trunk to subscribers in the community dial office where the trunk terminates, or via that community dial office to subscribers in a dial exchange beyond. This type of trunk may be desirable where excessive backhaul would otherwise be involved. In general, trunks of this type have disadvantages from an operating viewpoint for use with an operator office employing a large toll board because the supervision is different from that on regular operator office trunks. However, there may be cases where avoidance of long backhaul would result in appreciable savings.

There are two general types of dial back trunks:

1. Simple dial back, where the calling subscriber holds the line while the operator dials back over the same trunk to reach the called party.

2. Dual dial back, which functions similarly to (1) but also allows the operator to complete calls on a delayed basis. To complete a delayed call the operator first dials the calling party and upon answer she then proceeds to dial the called party over the same trunk. These trunks require circuits at the operator office which permit dialing back against either on-hook or off-hook supervision.

Stop-Dial Signals

Trunks from operators which terminate on line circuits or for other reasons are not prepared to receive dial pulses upon seizure should be arranged to give a stop-dial signal. This signal consists of an off-hook condition which should persist from immediately after seizure to the time the trunk is in condition to receive pulses. The stop-dial signal functions to stop operators or mechanical senders from pulsing to trunks before the circuits have conditioned themselves to receive pulses.

Figure 1. Tandem trunking arrangement for access by subscribers to operator only

Flashing Supervision to Operators

All circuits which complete calls from toll operators should be arranged to give the originating operator flashing supervision when a line busy or trunk busy condition is encountered. The speed of flashing for line busy is 60 interruptions per minute with tone and for trunks busy is 120 interruptions per minute without tone.

Control of the Connection

On calls between subscribers in the same exchange, the calling party usually has control of the connection. On calls from a subscriber to an operator, the connection should be jointly controlled by both subscriber and operator after answer by the operator. This arrangement permits the subscriber to flash the operator and also allows the operator to change cords, if necessary, without losing the connection. On calls from the operator to a community dial office subscriber the operator usually controls the connection. This arrangement allows the subscriber to flash but prevents him from holding a trunk out of service due to failure to hang up.

Traffic Registers

Traffic registers are provided to determine the amount of traffic handled by the office and also to determine if calls are being lost due to an insufficient amount of equipment. The following registers are usually provided:

1. Peg count register per finder group.
2. All finders busy register per finder group.
3. Peg count register per incoming selector group.
4. All trunks busy register per trunk group.
5. All trunks busy register for reverting call selectors.
6. Peg count register per connector or final group.

Terminal Per Line versus Terminal Per Station Service

Smaller community dial offices in rural areas are nearly always arranged to serve subscribers on a terminal per-line basis. This makes for economy in amounts of terminating equipment. However, some flexibility is sacrificed and the problem of providing intercept service, if required, is made more difficult and costly. In areas where these features may be required, it is desirable to serve subscribers on a terminal per-station basis. This is usually the case in offices exceeding roughly 500 lines in ultimate size and in all offices, regardless of size, which are located near metropolitan areas.

Transmission Balance

At the present time, with the expanding use of electric services in the rural areas, it is essential that transmission circuits be as carefully balanced as possible to avoid noise due to inductive interference. It is necessary to have the subscriber lines balanced as well as possible, but it also is necessary that all central office terminations which may be connected to these lines be carefully balanced.

Community dial offices frequently have to be arranged to give services that are not uniformly required in all offices. The most commonly encountered of these services are verification, intercepting, and message rate line circuits.

Verification

It is desirable that verification arrangements be provided where possible, particularly in offices near metropolitan centers, in order that emergency calls may be completed to busy lines. These facilities also permit verification of a line busy condition. In community dial offices verification calls are usually completed through the regular switch train by the operator dialing a preliminary or supplementary code in addition to the subscriber's number. The arrangement most generally used is to dial a code followed by the number to be verified. Verification facilities should be available to operators only. Wherever verification facilities are provided they should be of such a type as to permit a uniform method of operation with all the community dial offices involved.

Intercepting Service

Intercepting facilities are not ordinarily provided in offices of less than 500 lines unless the offices are adjacent to metropolitan areas, due to the cost of this type of equipment. In offices not equipped with intercept facilities, final terminals should not be made busy nor return the audible ringing signal to calling subscribers or operators, since these signals would be false indications. If intercept facilities are not used, it is desirable that the equipment be arranged so that no signal is returned on the call.

Message Rate Service

In some cases it may be necessary to serve a few lines on an individual line message rate basis. This is usually accomplished by the addition of an auxiliary circuit ahead of the regular line circuit. The auxiliary circuit operates the subscriber message register upon answer of

Figure 2. Tandem trunking arrangement with dual use trunks

the called party. To prevent improper operation of the circuit due to surges, a delay interval of 2 to 4 seconds is usually provided between the answer of the called party and the actual application of the charge condition.

Equipment Features

Simplified Installation

It is desirable that community dial equipment be designed in such a manner as to permit the maximum amount of wiring and cabling at the factory. This tends to reduce installation time on the job. The equipment may be arranged in unitized packages; these packages to be of such dimension and weight as to be handled easily in shipment and permit entrance through standard sized doors. For the very small sized offices, it may be possible to have the equipment for the entire office mounted on one such frame. For larger offices several frames may be required. Although it is desirable to have the equipment frames as small and compact as possible, care should be exercised to prevent crowding of apparatus and difficult access for maintenance. The total weight of the frame should not exceed reasonable permissible floor loading limits.

Adequate Traffic Capacity

The design of the frames should allow for an adequate number of switching paths to care for expected growth in lines and traffic. Although the initial installation may not require the frame or frames to be fully equipped, the ability to add circuit units as required as economically as possible is desirable. This may be accomplished in many cases by the use of "jacked-in" units.

Standard Floor Plan

Installations requiring two or more frames are usually arranged in accordance with an acceptable floor plan. Their location with respect to the distributing frame and power plant should be such as to permit short runs of cable. The distributing frame should provide space for an adequate number of protectors and be so arranged as to permit easy access for changing cross connections for subscriber moves and disconnects. The battery charging plant should have ample capacity to maintain the battery in a charged condition during the busy hour load. The storage battery should have ample reserve capacity to protect against office failure during times of commercial power stoppages. The necessary reserve for any particular office is usually determined by an estimate of the reliability of the commercial power service, and will vary in different areas.

Table I

	Alarm Transmitted after Delay of:	Signal on Checking Terminal
Major Alarms		
Main and common fuses blown	0	No tone
Ringing failure	1–4 minutes	No tone
Low or high voltage	1–4 minutes	No tone
Master charge control relay failure	1–4 minutes	No tone
Line finders blocked	1–4 minutes	No tone
Excessive Number of Permanents	0	Dial tone
Minor Alarms		
Individual fuses blown	0	Busy tone
Ringing transfer	1–4 minutes	Busy tone
Release magnet failure	1–4 minutes	Busy tone
Permanent signals less than excess number	20–60 minutes	1-ring code
No trouble		2-ring code

Maintenance Facilities

Alarms

Since community dial office equipment is unattended, means may be provided to supervise the operating condition of the office. This is accomplished by providing a final terminal as an alarm checking terminal. Whenever this terminal is dialed by the distant operator or maintenance man, the presence of tones or lack of tone indicates the condition of the office. In addition to the alarm checking terminal, an alarm sender is usually provided. When a trouble condition occurs at the community dial office the alarm sender seizes a regular trunk to the operator office. When the operator answers, no special indication of the trouble is given. It appears to be an abandoned call except the cord supervisory lamp remains dark and the trunk does not release until the alarm checking terminal has been dialed. The operator dials the number of the alarm checking terminal over another trunk and receives a tone signal indicating the class of alarm. The dialing of the alarm checking terminal also releases the trunk used by the alarm sender. Where trunks are arranged for dial back operation, the operator dials the alarm checking terminal back over the same trunk over which the alarm signal was received. When an alarm sender is not used the operator must dial the alarm checking terminal periodically to determine if a trouble condition exists. When an operator receives an alarm indication she refers it to proper channels for action.

The signals given in Table I are usually used to indicate the class of alarm when the alarm checking terminal is called.

General Maintenance Facilities

As stated before, easy access to all apparatus greatly facilitates maintenance. In many cases most routine tests and maintenance operations will be performed by personnel who spend only a part of their time working with central office equipment. Therefore, it is important that testing procedures be as simple and straightforward as possible. Most of these tests can be in the nature of operational tests. The circuits employed in community dial offices should be simple and the use of marginal operating arrangements avoided where possible. Simple make-busy arrangements should be provided to hold circuits which are in trouble out of service. In general, fewer common circuits and relatively simple circuit design will result in easier maintenance of the equipment.

Community dial office equipment should be so designed as to furnish all the necessary services required with the minimum maintenance attention. The circuit arrangements should be simple and easily understandable. The equipment should be rugged in design so as to be suitable for operation in buildings which will have a minimum of heating in winter, yet not be affected by high summer temperatures. It is desirable that expansion due to growth or additional features should require a minimum of engineering and installation effort.

No Discussion

Some Aspects of Lightning Surges on Power Systems and Their Suppression

S. KANEFF
ASSOCIATE AIEE

Synopsis: The paper points out that lightning surges contain an infinite band of frequency components and for this reason, the behavior of a system to surges depends on its impedance characteristics over a wide range of frequencies.

A capacitive-inductive suppression device is suggested and design details and test results given. This device is most effective for short-duration steep-sided surges. At present, it seems practicable for lower voltage circuits but if cheaper capacitors can be constructed, it also could be used for higher voltages.

An aspect of power systems not usually considered by power engineers is that of behavior at frequencies well above the generated frequency.

Although not of interest during normal conditions, this behavior becomes important when surges, especially due to lightning, impinge on the system. Lightning surges contain (as indicated in the following section) an infinite band of frequencies, and it is clear that impedance characteristics should be known over a wide range of frequencies in order that a clear picture be obtained of system behavior when subjected to surges.

Considering lightning surges in terms of frequency components suggests suppression devices similar to communication-type low-pass filters and consisting of capacitors and inductances.

At present such protection seems to be practicable for low-voltage circuits, where it should find many applications, but an obvious objection for high voltages is the cost of capacitors. However, high-voltage capacitors are being used more extensively (for example, for power-factor correction, carrier-system coupling units, potential dividers, and so forth) and it is possible that with improvements in techniques, capacitors may be economically available for the higher-voltage systems also.

Amplitude-Frequency Spectrum Analysis

As is well known, lightning surges can be expressed mathematically by the relation

$$f(t) = E(e^{-at} - e^{-bt}) \tag{1}$$

Surges can be represented with sufficient accuracy by equation 1 by suitably choosing the parameters a, b, and E, Figure 1.

It is proved in mathematical texts that if a function in time, $f(t)$, can be represented as

$$f(t) = \int_{-\infty}^{\infty} g(\omega) d\omega e^{j\omega t} \tag{2}$$

then it can be converted into a frequency function

$$g(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} f(t) dt e^{-j\omega t} \tag{2}$$

subject to certain restrictions which are, however, fulfilled by any practical function, see the appendix and reference 1.

The frequency function for a lightning surge represented by equation 1 is then given by

$$g(\omega) = \frac{E}{2\pi} \left\{ \left(\frac{1}{a+j\omega} - \frac{1}{b+j\omega} \right) \right\}$$

and the amplitude-frequency spectrum is

$$|g(\omega)| = \frac{E(b-a)}{2\pi\sqrt{a^2b^2+\omega^4+\omega^2(a^2+b^2)}} \tag{3}$$

see Appendix.

Figure 2(B) shows amplitude-frequency spectra for four typical surges, the ordinate at any abscissa value gives the actual amplitude of the sinusoidal component of that frequency.

From equation 3 and from Figure 2 it is evident that:

1. All frequencies from zero to infinity are present in the surge.
2. As the duration of the loop of the surge increases, the spectrum height increases for the lower frequencies and decreases for the higher—more of the energy being concentrated in the lower-frequency components—and conversely, the shorter the loop, the more is the energy concentrated in high frequencies.
3. In general, the most destructive surges have a comparatively short loop and steep sides, these have most of their energy in the higher frequencies.

It follows then, that if a clear physical picture is to be obtained of the behavior of a system subjected to lightning surges, it is necessary to know its impedance-frequency characteristic from power-frequencies up to quite high frequencies. If this characteristic is known, then a better understanding will be reached as to the

Figure 1. Typical lightning surge

Paper 50-250, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23-27, 1950. Manuscript submitted May 15, 1950; made available for printing September 5, 1950.

The author wishes to express his appreciation for the co-operation shown by the Electricity Trust of South Australia in allowing him the use of equipment and personnel for his tests. Thanks are due to R. E. Vowels and E. Heider for valuable suggestions, while special acknowledgment is due to Professor E. O. Willoughby who suggested the research and under whose direction it was conducted. The author also wishes to acknowledge the assistance received from the Electricity Supply Association of Australia, by the provision of funds through the Electrical Research Board.

type and characteristics of protection devices required.

Requirements of a Suppression Device

From the previous section it is seen that the complete suppression of a surge involves the elimination of a band of frequencies from zero to infinity.

Practically, complete suppression is unnecessary; it is sufficient that the amplitude and steepness of a surge be reduced to values permitted by the strength of protected apparatus.

In terms of the amplitude-frequency spectrum, for effective suppression, as many of the frequency components as is practicable, should be eliminated.

T, π, L Networks as Surge Suppressors

The problem of suppressing a band of frequencies above the transmitted (power) frequency is solved in communication circuits by low-pass filters—T, π, or L networks in the simplest form, see Figure 3(A).

Such networks should, therefore, suppress lightning surges.

Theory

The method of connecting the network in a power circuit is indicated in Figure 4(A) and (B). Figure 3(B) shows the well-known attenuation characteristic of a low-pass filter. For the present discussion, it is convenient to consider this in a slightly different form as in Figure 3(C), where ordinate values represent the quantity:

$$\frac{\text{Output Voltage from Filter}}{\text{Input Voltage to Filter}}$$

at each frequency. At any given frequency, this curve shows what fraction of the amplitude of that particular frequency component is transmitted by the suppression network, and what fraction is suppressed.

Applying the curve in Figure 3(C) to the amplitude-frequency spectrum of an incident surge will give the amplitude-frequency spectrum of the surge emerging from the suppression network. In Figure 2(B), this has been done for the surges of Figure 2(A). The full lines represent the amplitude-frequency spectrum of the incident surge and the dotted lines that of the transmitted surge.

It will be noted that the network has eliminated the higher frequencies, leaving low-frequency components only. This indicates that the surge transmitted by the suppression network has been reduced in amplitude and steepness and lengthened in time. This is confirmed by the output surges as calculated in the Appendix and recorded in Figure 2(C).

The effect of the T, π, or L network is, therefore, to reduce the surge in amplitude and steepness and to lengthen it in time; that is, to render it less harmful. The network acts for surges of any magnitude (unlike spark-gap devices, which act only after the voltage has attained a certain amplitude.)

Figure 2. Amplitude-frequency spectra and network suppression

(A) Incident surge
(B) Amplitude-frequency spectrum
(C) Output surge from suppression network

Design

The following sections indicate the manner of designing a T, π, or L network for a practical setup.

Equations

The algebraic relations for low-pass filters (as given in any elementary text) are:

$$R = \sqrt{\frac{L_1}{C_1}} = \text{characteristic impedance, line to earth} \quad (4)$$

$$f_c = \frac{1}{\pi\sqrt{L_1 C_1}} = \text{cut-off frequency of the filter} \quad (5)$$

Figure 3 (left). Low-pass filters—T, π, L networks
(A) Circuit arrangement
(B) Attenuation characteristic
(C) New form of attenuation characteristic

Figure 4 (above). Method of connecting suppression network
(A) In general
(B) Using T network in 3-phase line

$$L_1 = \frac{R}{\pi f_c} \tag{6}$$

$$C_1 = \frac{1}{\pi f_c R} \tag{7}$$

Equations 4, 5, 6, and 7 then enable the networks to be designed.

The suppression network is matched to the line by making R of network = characteristic impedance, line to earth, so preventing reflections of surges due to insertion of the network.

Choice of R and f_c

The characteristic impedance, R, is fixed by the geometry of the transmission line and can be found by calculation. The choice of cut-off frequency, f_c, however, is dictated by economic considerations.

Table I shows size of components for various cut-off frequencies for characteristic impedances of 400 ohms and 600 ohms, most lines having values of this order.

Practical tests have indicated that f_c need not be below 10 kc for effective suppression. At present, such a cut-off frequency appears to be economically practicable for voltages below 66 kv, but for higher voltages, the cost of capacitors would be large. However, with improved techniques, it is possible that cheaper capacitors may be made for even the highest voltages, as high-voltage capacitors are being used more and more extensively.

Table I. Network Constants

Cut-off Frequency, f_c, cycles	R = 400 Ohms L_1, Millihenrys	R = 400 Ohms C_1, Microfarads	R = 600 Ohms L_1, Millihenrys	R = 600 Ohms C_1, Microfarads
5,000	25.5	0.16	38.2	0.107
10,000	12.75	0.08	19.1	0.053
20,000	6.38	0.04	9.55	0.0265

Choice of T, π, or L—Impedance Considerations

Table II indicates where the different configurations may be used to greatest advantage.

From the viewpoint of reliability, the T or L would probably be best, due to the protection offered C_1 by the first inductance.

A knowledge of the impedance frequency characteristics of protected equipment is desirable, as this allows a proper design of protection to be made. Figure 5 shows the impedance frequency properties of a small substation, Figure 5(A), and also a large switchyard, Figure 5(B). In the first case, the terminal impedance is mainly high and π suppression would be recommended, while in the second, the impedance is low and T suppression would be best. (L suppression could be used for either case.)

Suppression of Ringing

To prevent ringing of the suppression networks due to steep-sided surges, the

Table II

Network	Remarks	Recommended for Following Terminations	Examples of Where Beneficial
Surge T 	C_1 is protected from full surge by $L_{1/2}$. T presents high impedance in either direction	Low impedance capacitive and inductive	Large substations and large transformers
Surge π 	First $C_{1/2}$ unprotected from full surge. π presents low impedance either way	Inductive or capacitive. High impedance	Small substations and small transformers. Rotating machines
Surge L 	For given f_c, suppression not as good as T or π, but cheaper	Capacitive or inductive.	Substations, transformers, and rotating machines

inductances must be damped by resistors. If resistive ohms = numerically reactive ohms of inductance at f_c, then volt amperes/watt ratio for the resistive inductive branch will be equal to, or less than, unity for frequencies at and below f_c, and no ringing will occur.

The capacitors should be protected against exceedingly high voltages (in excess of maximum capacitor strength) by spark gaps—necessary for the π network, but not so important for T and L, as the capacitor is connected to a low-voltage point in the latter cases.

Effect of Suppression Device on Power-Frequency Operation

A practical suppression network will have negligible effect on the operation at power frequencies. For example, the network used in Figure 6(A) corresponds to a length of line of the order of two miles (as far as reactance is concerned).

Results of Tests

Figure 6 records tests carried out using recurrent surge oscilloscope equipment. Figure 6(A) shows the suppression of various surges obtained from a π network of $R = 400$ ohms and $f_c = 12.5$ kc. Figure 6(B) shows the suppression produced by a T network of $R = 600$ ohms and $f_c = 12.5$ kc connected at the end of a 33-kv transmission line $2^1/_4$ miles long. This demonstrates that a network of $f_c = 12.5$ kc would be satisfactory in practice.

Effectiveness

Figure 2(C) and Figures 6(A) and (B) indicate that the effectiveness of the T, π, L networks decreases as the surge becomes longer and less steep, and increases as the surge becomes steeper and shorter.

Uses

T, π, or L suppression networks can be used wherever lightning protection is required, for the protection of substations, transformers, and particularly for machines connected directly to transmission lines (where it is important that no steep-sided surges enter the machine).

Where capacitors are already in use on lines and equipment, it may be possible by adding inductances to build up T, π, or L networks for more effective surge suppression; for example, capacitors are often used for surge modification on machines connected directly to transmission lines, in this case, the addition of inductance would be a simple matter.

Figure 5. Impedance-frequency characteristics

(A) Small substation (B) Section of power station switchyard

Conclusions

Lightning surges can be analysed into a system of components having all frequencies from zero to infinity. Most of the energy of long flat surges is in the lower frequencies, while for short steep surges (generally the most destructive), the energy is mainly in the higher frequencies. A knowledge of impedance-frequency characteristics of systems over a wide range of frequencies is desirable.

T, π, L networks will suppress lightning surges, most effectively for short steep surges.

1. The networks reduce a surge in amplitude and steepness and prevent oscillations in terminal equipment. The networks act for surges of any amplitude.

2. They can cause no reflections (since they are matched to the line) and voltage cannot build up between themselves and protected equipment due to reflection.

3. For given cut-off frequency, a T network is best; L is most economical but not as good a suppressor.

4. T, π, L networks have negligible effect on the power-frequency operation of a system.

5. Where capacitors are already used, it may be possible by adding inductances to form T, π, or L networks for better suppression.

6. T, π, L networks will suppress the frequency components above f_c of any surge, switching, and so forth.

7. At present, these networks appear to be practicable for voltages below 66 kv. With improved techniques in capacitor manufacture, it may be possible that the networks also will be feasible for much higher voltages.

Appendix

Frequency Spectrum of Surges

$$f(t) = E(e^{-at} - e^{-bt}) \tag{8}$$

It is proved in textbooks of mathematics that, if a function in time, $f(t)$ can be represented as

$$f(t) = \int_{-\infty}^{\infty} g(\omega)\, d\omega\, e^{j\omega t} \tag{9}$$

then it can be converted into a frequency function

$$g(\omega) = \frac{1}{2\pi}\int_{-\infty}^{\infty} f(t)\, dt\, e^{-j\omega t} \tag{9}$$

This is the Fourier Integral in a general form.

The restrictions on $f(t)$ are:

1. $f(t)$ must be continuous over intervals of finite length. At points of discontinuity, say at $t = a$, the value of the function shall be understood to be the arithmetical mean; that is

$$f(a) = {}^1/_2\{f(a-0) + f(a+0)\}$$

2. The integral of the magnitude of $f(t)$ over the region

$-\infty < t < \infty$ must be finite

that is,

$\int_{-\infty}^{\infty} |f(t)|\, dt$ must exist

Any practical function fulfils these conditions, see Reference 1. In equation 8, $f(t)$ is defined as follows:

$f(t) = 0$, for $t < 0$

$f(t) = E(e^{-at} - e^{-bt})$ for $t > 0$

where a and b are real.

Then the frequency spectrum is given by:

$$g(\omega) = \frac{1}{2\pi}\int_{-\infty}^{\infty} f(t)\, dt\, e^{-j\omega t}$$

$$= \frac{E}{2\pi}\left(\int_{0}^{\infty} e^{-(a+j\omega)t}\, dt - \int_{0}^{\infty} e^{-(b+j\omega)t}\, dt\right)$$

$$= \frac{E}{2\pi}\left(\frac{1}{a+j\omega} - \frac{1}{b+j\omega}\right)$$

This is complex and can be separated into an amplitude spectrum and a phase spectrum. Only the amplitude spectrum is of interest here, and so

$$g(\omega) = \frac{E}{2\pi}\left(\frac{1}{a+j\omega} - \frac{1}{b+j\omega}\right)$$

$$= \frac{E(b-a)}{2\pi}\left\{\frac{(ab-\omega^2) - j\omega(b+a)}{(ab-\omega^2)^2 + \omega^2(b+a)^2}\right\}$$

$$\therefore |g(\omega)| = \frac{E(b-a)}{2\pi}\cdot\frac{1}{\sqrt{a^2b^2 + \omega^4 + \omega^2(a^2+b^2)}} \tag{10}$$

Then equation 10 gives the required amplitude-frequency spectrum and can be plotted to a frequency scale, given a, b, and E.

Any practical wave can be treated in this way; for example, Figure 2.

Output Waveform from Suppression Network

As the network cannot be considered alone, some terminating impedance (z), must be specified. For simplicity, let it be

resistive and equal to R_1, Figure 7.

It is required to find the voltage v, across R_1, when a surge V is applied to the π-type suppression network.

Using the Laplace Transform method of solution, let $v(p)$ represent the transform of output voltage, and let $V(p)$ represent the transform of input voltage.

Then,

$$v(p) = \frac{V(p)\dfrac{2}{Cp}R_1}{\dfrac{2}{Cp}+R_1} \times \left(\frac{R_2Lp}{R_2+Lp} + \frac{\dfrac{2}{Cp}R_1}{\dfrac{2}{Cp}+R_1}\right) = V(p)\frac{2}{R_2C}\times \left\{\frac{\left(p+\dfrac{R_2}{L}\right)}{\left[p+\left(\dfrac{1}{CR_1}+\dfrac{1}{CR_2}\right)\right]^2+\dfrac{2}{LC}-\left(\dfrac{1}{CR_1}+\dfrac{1}{CR_2}\right)^2}\right\}$$

$$= V(p)\frac{2}{R_2C}\left\{\frac{(p+a_4)}{(p+\alpha)^2+\beta^2}\right\} \quad (11)$$

Figure 7. π section subjected to a surge

where $a_4 = R_2/L$ and $\alpha = \left(\dfrac{1}{CR_1}+\dfrac{1}{CR_2}\right)$

$$\beta^2 = \left[\frac{2}{LC} - \left(\frac{1}{CR_1}+\frac{1}{CR_2}\right)^2\right]$$

If

$$V = f(t) = E(\epsilon^{-at} - \epsilon^{-bt})$$

is applied to the network, then

$$V(p) = E\left(\frac{1}{(p+a)} - \frac{1}{(p+b)}\right)$$

$$\therefore v(p) = \frac{2E}{R_2C}\left(\frac{1}{p+a} - \frac{1}{p+b}\right)\cdot\left(\frac{(p+a_4)}{(p+\alpha)^2+\beta^2}\right)$$

from equation 11. This gives

$$v = \frac{2E}{R_2C}\left\{\left[\frac{a_4-a}{(\alpha-a)^2+\beta^2}\right]\cdot\epsilon^{-at} + \frac{1}{\beta}\left[\frac{(a_4-a)^2+\beta^2}{(a-\alpha)^2+\beta^2}\right]^{1/2}\cdot\epsilon^{-\alpha t}\sin(\beta t+\psi_1) - \left[\frac{a_4-b}{(\alpha-b)^2+\beta^2}\right]\cdot\epsilon^{-bt} - \frac{1}{\beta}\left[\frac{(a_4-\alpha)^2+\beta^2}{(b-\alpha)^2+\beta^2}\right]^{1/2}\cdot\epsilon^{-\alpha t}\sin(\beta t+\psi_2)\right\} \quad (12)$$

where

$$\left[\left(\psi_1 = \arctan\frac{\beta}{a_4-\alpha} - \arctan\frac{\beta}{a-\alpha}\right.\right.$$

$$\left.\left.\psi_2 = \arctan\frac{\beta}{a_4-\alpha} - \arctan\frac{\beta}{b-\alpha}\right)\right]$$

Equation 12 gives the output wave from the network. This has been used in Figure 2(C) to obtain the output waves shown.

No Discussion

Synchronous Machine Damping Torque at Low Speeds

CHARLES CONCORDIA
FELLOW AIEE

IN connection with the problem of starting two electrically connected synchronous machines from rest,[1] damping torque is one of the important factors. This has been indicated by the results of the approximate starting performance calculations neglecting rotor resistances presented in reference 1, which show in some cases amplifying oscillations after synchronizing sufficiently severe to cause loss of synchronism. The object of this paper is to show the magnitudes and characteristics of the damping torque as affected by the various system parameters, including the rotor circuits.

The observed tendency toward negative damping may be explained qualitatively by noting that operation at low speed is roughly equivalent to operation with high armature resistance, and it has been known[2] for a long time that high armature resistance tends to produce a component of negative damping in a synchronous motor or generator operating in parallel with other synchronous machines. On the other hand, if the armature resistance becomes extremely high, its contribution is a component of positive damping torque.[3] Both of these previous conclusions are found to be in accord with the results obtained in the present study.

Two Round Rotor Machines—Rotor Circuits Neglected

As an approximation to the actual conditions, small oscillations, at a prescribed frequency, about a constant average synchronous speed have been assumed. Then if rotor windings are neglected and $x_d = x_q$ for both machines, the system equations are:[4]

$$(px+r)i_{d1} - xi_{q1}p\theta_1 = E_2 \sin(\theta_2-\theta_1)p\theta_2$$
$$xi_{d1}p\theta_1 + (px+r)i_{q1} = E_1 p\theta_1 - E_2\cos(\theta_2-\theta_1)p\theta_2 \quad (1)$$

$$M_1 p^2\theta_1 = -E_1 i_{q1} - T_{L1}$$
$$M_2 p^2\theta_2 = E_2[i_{q1}\cos(\theta_2-\theta_1) - i_{d1}\sin(\theta_2-\theta_1)] - T_{L2} \quad (2)$$

where

$M = 4\pi fH$ = rotor inertia
r = total armature circuit resistance
x = total armature circuit reactance
θ = machine angle
i_d = direct-axis component of armature current
i_q = quadrature-axis component of armature current
E = equivalent rotor excitation
T = prime mover or load torque
Subscripts 1 and 2 refer to the two interconnected machines

For small oscillations about an average speed ω, equations 1 become, on dropping the current subscripts and letting $\theta_1 - \theta_2 = \delta$

$$(px+r)\Delta i_d - (\omega x)\Delta i_q = (xi_{q0}p - E_2\omega\cos\delta_0)\Delta\theta_1 + (-E_2\sin\delta_0 p + E_2\omega\cos\delta_0)\Delta\theta_2$$
$$(\omega x)\Delta i_d + (px+r)\Delta i_q = (E_1 p - xi_{d0}p + E_2\omega\sin\delta_0)\Delta\theta_1 - (E_2\cos\delta_0 p + E_2\omega\sin\delta_0)\Delta\theta_2 \quad (3)$$

Solving for Δi_d, Δi_q,

$$D\Delta i_d = [(\omega x)(-xi_{d0}p + E_1 p + E_2\omega\sin\delta_0) + (px+r)(xi_{q0}p - E_2\omega\cos\delta_0)]\Delta\theta_1 + [(px+r)(-E_2\sin\delta_0 p + E_2\omega\cos\delta_0) - (\omega x)(E_2\cos\delta_0 p + E_2\omega\sin\delta_0)]\Delta\theta_2 \quad (4)$$
$$D\Delta i_q = [(px+r)(-xi_{d0}p + E_1 p + E_2\omega\sin\delta_0) - (\omega x)(xi_{q0}p - E_2\omega\cos\delta_0)]\Delta\theta_1 - [(\omega x)(-E_2\sin\delta_0 p + E_2\omega\cos\delta_0) + (px+r)(E_2\cos\delta_0 p + E_2\omega\sin\delta_0)]\Delta\theta_2$$

where

$$D = (\omega^2+p^2)x^2 + r^2 + 2xrp$$

From equations 1, the required steady-state currents are:

$$Di_{d0} = -\omega r E_2\sin\delta_0 + \omega^2 x(E_1 - E_2\cos\delta_0)$$
$$Di_{q0} = \omega r(E_1 - E_2\cos\delta_0) + \omega^2 x E_2\sin\delta_0 \quad (5)$$

where

$$D_0 = r^2 + \omega^2 x^2$$

It also is evident from equations 4 that the relative magnitudes of $\Delta\theta_1$ and $\Delta\theta_2$ affect the torque. The amplitudes of the natural-frequency components of the machine oscillations (which are the principal components during the starting periods considered here) will be very nearly in the ratio

$$\frac{\Delta\theta_1}{\Delta\theta_2} = -\frac{M_2}{M_1} \quad (6)$$

The cases studied have involved machines of unequal inertias, the generator inertia being roughly twice the motor inertia and the total effective inertia being such as to make the per-unit natural frequency s about 0.02. For example, in the work reported in reference 1, $H_1 = 5.0$ and $H_2 = 2.55$ in most of the cases. The natural frequency is approximately given by the formula:

$$s^2 \cong \frac{T_s\ (\text{avg})}{M}$$

where

$$M = \frac{M_1 M_2}{M_1 + M_2}$$

CASE 1, $E_1 = E_2 = 1.0$, $\delta = 0$

With no steady load and equal (unit) excitations, there is:

$$E_1 = E_2 = 1.0$$
$$\delta_0 = 0$$
$$i_{d0} = i_{q0} = 0$$

Equation 4 for Δi_q is then reduced to

$$\Delta i_q = \frac{[(px+r)p + \omega^3 x]}{(p^2+\omega^2)x^2 + r^2 + 2xrp}\Delta\delta = \Delta T_1 \quad (7)$$

where $\Delta\delta = \Delta\theta_1 - \Delta\theta_2$ and T_1 = electrical torque on machine 1.

Equation 7 is valid for either machine. For an oscillation frequency s, $p = js$, and[4]

$$\frac{\Delta T_1}{\Delta\delta} = \frac{(\omega^2 - s^2)x + jrs}{(\omega^2 - s^2)x^2 + r^2 + j2xrs} = T_s + jsT_d \quad (8)$$

Paper 50-252, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted June 19, 1950; made available for printing August 30, 1950.

CHARLES CONCORDIA is in the Analytical Division of the General Electric Company, Schenectady, N. Y.

Figure 1 (left). Damping torque coefficient for oscillations at frequency s, of two synchronous machines running at low speed ω

$E_1=E_2=1.0$; $\delta=0$; $x=1.0$; $r=0.01$
Curve A, $s=0$; B, 0.01; C, 0.02; D, 0.5ω; E, ω

Figure 3 (right). Damping torque coefficient for oscillations at frequency s, of two synchronous machines running at low speed ω

Effect of Unequal Excitations

$E_g=1.0$; $E_m=0.5$; $\delta=0$; $x=1.0$; $r=0.01$
Curve A, $s=0$; B, 0.01; C, 0.02; D, ω

Then the damping torque coefficient T_d is

$$T_d=\frac{[r^2-(\omega^2-s^2)x^2]r}{[(\omega^2-s^2)x^2+r^2]^2+(2xrs)^2} \tag{9}$$

T_d is therefore negative, and the oscillations consequently unstable, for

$$r^2-(\omega^2-s^2)x^2<0 \tag{10A}$$

or

$$\omega^2>\frac{r^2}{x^2}+s^2 \tag{10B}$$

or

$$s^2<\omega^2-\frac{r^2}{x^2} \tag{10C}$$

Note that equation 10A may be regarded as related to conclusion 2 of reference 3, in that for $s=0$, r must be greater than ωx for stable operation.

If $r=0$, equations 10 are invalid and $T_d=0$. The synchronizing torque coefficient T_s is

$$T_s=\frac{[(\omega^2-s^2)^2x^2+(\omega^2+s^2)r^2]x}{[(\omega^2-s^2)x^2+r^2]^2+(2xrs)^2} \tag{11}$$

Figures 1 and 2 show the damping and synchronizing torque coefficients respectively for the five cases,

$s=0, 0.01, 0.02, 0.5\omega, \omega$
$E_1=E_2=1$, $\delta=0$
$x=1.0$, $r=0.01$
$0<\omega<0.04$

From Figure 1 it is seen that, for all cases except $s=\omega$, the damping torque is first positive at very low speeds, then becomes negative and reaches a maximum negative value at $\omega\geqslant 0.02$, then decreases again and finally approaches zero at infinite speed. It is to be noted that the criteria developed by Nickle and Pierce[2] show this system to be unstable at normal speed, and, therefore, lead to correct results except for $s=\omega$, which is outside of the range of oscillation frequencies considered in their work. In Figure 2 the interesting feature is the marked dip in the synchronizing torque at constant oscillation frequency near the point $s=\omega$.

Case 2. $E_1\neq E_2$, $\delta=0$

Next the effect of unequal excitations is studied. With $\delta=0$ and $\Delta\theta_2=-\Delta\theta_1$, equations 4 and 5 yield for the damping torque coefficient of machine 1:

$$T_d=\frac{[r^2-(\omega^2-s^2)x^2]rE_1(E_1+E_2)}{2\{[(\omega^2-s^2)x^2+r^2]^2+(2xrs)^2\}} \tag{12}$$

By comparing equations 12 and 9, it is seen that with $\Delta\theta_2=-\Delta\theta_1$, the form of T_d as a function of ω and s is unchanged, and the only effect of unequal excitations is to make T_d proportional to the product of the excitation (E_1) on machine 1 and the average excitation $1/2\ (E_1+E_2)$. Equations 10 are thus still valid.

Figures 3 and 4 show the damping torque coefficients of both machines, when the ratio of excitations is one half, for the four cases,

Figure 2 (left). Synchronizing torque coefficient for oscillations at frequency s, of two synchronous machines running at low speed ω

$E_1=E_2=1.0$; $\delta=0$; $x=1.0$; $r=0.01$

Figure 4 (right). Damping torque coefficient for oscillations at frequency s, of two synchronous machines running at low speed ω

Effect of Unequal Excitations

$E_g=1.0$; $E_m=0.5$; $\delta=0$; $x=1.0$; $r=0.01$
Curve A, $s=0$; B, 0.01; C, 0.02; D, ω

Figure 5 (left), Figure 6 (right). Damping torque coefficient for oscillations at frequency s, of two synchronous machines running at low speed ω

Effect of Load Angle
$E_1 = E_2 = 1.0$; $\delta_{2m} = \theta_g - \theta_m = 30°$; $x = 1.0$; $r = 0.01$
Curve A, $s = 0$; B, 0.01; C, 0.02; D, ω

$s = 0, 0.01, 0.02, \omega$
$\delta = 0$
$E_g = 1.0$; $E_m = 0.5$; $g, m = 1,2$
$x = 1.0$, $r = 0.01$
$0 < \omega < 0.04$
$\Delta\theta_2 = -\Delta\theta_1$

From the last condition,

$$\frac{\Delta\theta_1}{\Delta\delta} = 0.5; \quad \frac{\Delta\theta_2}{\Delta\delta} = -0.5$$

From Figures 3 and 4 or equation 12 the damping torque coefficient for the machine with unit excitation is three quarters of that for the case of unit excitation on both machines, while the damping torque coefficient for the machine with 0.5 excitation is only three eighths of that for the case of unit excitation on both machines.

CASE 3. $E_1 = E_2 = 1.0$, $\delta \neq 0$

As the next step, the effect of load angle is studied. (Consideration of a load angle may be expected to indicate in some degree the effects of acceleration.) Figures 5 and 6 show the results for the four cases

$s = 0, 0.01, 0.02, \omega$
$\delta_{2m} = \theta_g - \theta_m = 30°$
$E_1 = E_2 = 1.0$
$x = 1.0$, $r = 0.01$
$0 < \omega < 0.04$
$\Delta\theta_2 = -\Delta\theta_1$

Comparing Figures 5 and 6 to Figure 1, it is seen that with $\Delta\theta_2 = -\Delta\theta_1$, load angle increases the damping torque of the motor (machine m) and decreases that of the generator (machine g), except for very small speeds ω, where the damping torques of both machines are decreased. At zero speed the torques are decreased by about 6.7 per cent.

Effect of Rotor Circuits

If the effects of rotor circuits are included, equations 3 may be shown to become:[4]

$$[\cos\delta_{120}(z_{d1}(p)+z_{d2}(p)) - \omega\sin\delta_{120}(x_{d1}(p)+x_{q1}(p))]\Delta i_{d1} - [\sin\delta_{120}(z_{q1}(p)+z_{q2}(p)) + \omega\cos\delta_{120}(x_{q1}(p)+x_{q2}(p))]\Delta i_{q1} = -[e_{d20} + i_{q20}\omega x_{q2}(p) + i_{q20}z_{q2}(p) + \sin\delta_{120}\psi_{d10}p + \cos\delta_{120}\psi_{q10}p]\Delta\delta_1 + [e_{q20} + i_{d20}\omega x_{q2}(p) + i_{q20}z_{q2}(p) + \psi_{q20}p]\Delta\delta_1 = -[e_{q20} + i_{q20}\omega x_{q2}(p) + i_{q20}z_{q2}(p) + \psi_{q20}p]\Delta\delta_{12} + [(\psi_{q20} - \psi_{d10}\sin\delta_{120} - \psi_{q10}\cos\delta_{120})p]\Delta\delta_1 \quad (13A)$$

$$[\sin\delta_{120}(z_{d1}(p)+z_{q2}(p)) + \omega\cos\delta_{120}(x_{d1}(p)+x_{d2}(p))]\Delta i_{d1} + [\cos\delta_{120}(z_{q1}(p)+z_{q2}(p)) - \omega\sin\delta_{120}(x_{q1}(p)+x_{d2}(p))]\Delta i_{q1} = [e_{d20} + i_{d20}z_{q1}(p) - i_{q20}\omega x_{d2}(p) + \cos\delta_{120}\psi_{d10}p - \sin\delta_{120}\psi_{q10}p]\Delta\delta_1 - [e_{d20} + i_{d20}z_{q2}(p) - i_{q20}\omega x_{d2}(p) + \psi_{d20}p]\Delta\delta_2 = [e_{d20} + i_{d20}z_{q2}(p) - i_{q20}\omega x_{d2}(p) + \psi_{d20}p]\Delta\delta_{12} + [(\psi_{d10}\cos\delta_{120} - \psi_{q10}\sin\delta_{120} - \psi_{d20})p]\Delta\delta_1 \quad (13B)$$

where $z(p) = px(p) + r$.

The required steady-state quantities are given by

$$D_0 i_{d20} = \left[r - \frac{\omega}{2}(x_{q1} - x_{d1})\sin 2\delta_{120}\right] \times \omega E_1 \sin\delta_{120} + \left[x_{q1} + \frac{(x_{q1}+x_{d1})}{2} + \frac{(x_{q1}-x_{d1})}{2}\cos 2\delta_{120}\right] \times \omega^2(E_2 - E_1\cos\delta_{120}) \quad (14)$$

$$D_0 i_{q20} = \left[r + \frac{\omega}{2}(x_{q1} - x_{d1})\sin 2\delta_{120}\right] \times \omega(E_2 - E_1\cos\delta_{120}) - \left[x_{d1} + \frac{(x_{q1}+x_{d1})}{2} - \frac{(x_{q1}-x_{d1})}{2}\cos 2\delta_{120}\right] \times \omega^2 E_1 \sin\delta_{120}$$

where

$$D_0 = r^2 + \omega^2[x_{q1}x_{d1} + x_{q2}x_{d2} + 0.5(x_{q1}+x_{d1})(x_{q2}+x_{d2}) - 0.5(x_{q1}-x_{d1})(x_{q2}-x_{d2})\cos 2\delta_{120}]$$

$$\psi_{d20} = E_2 - x_{d2}i_{d20}$$
$$\psi_{q20} = -x_{q2}i_{q20} \quad (15)$$

$$e_{d20} = -r_2 i_{d20} - \omega\psi_{q20}$$
$$e_{q20} = -r_2 i_{q20} + \omega\psi_{d20} \quad (16)$$

$$i_{d10} = -i_{d20}\cos\delta_{120} - i_{q20}\sin\delta_{120}$$
$$i_{q10} = +i_{d20}\sin\delta_{120} - i_{q20}\cos\delta_{120} \quad (17)$$

$$\psi_{d10} = E_1 - x_{d1}i_{d10}$$
$$\psi_{q10} = -x_{q1}i_{q10} \quad (18)$$

The torque is now

$$\Delta T_1 = (\psi_{d10} + i_{d10}x_{q1}(p))\Delta i_{q1} - (\psi_{q10} + i_{q10}x_{d1}(p))\Delta i_{d1} = (T_s + jsT_d)\Delta\delta_{12} \quad (19)$$

In order to determine the amortisseur characteristics required to insure positive

* This table follows the notation of reference 5 giving the self and mutual inductance coefficients of the various machine windings.

Figure 7. Damping torque coefficient of oscillations at frequency s, of two synchronous machines running at low speed ω

Effect of Amortisseur

Points ⊙ are for $\delta_{120} = -30°$, $\Delta\theta_2 = -0.5\Delta\theta_1$

Point a, machine 1 } Amortisseur in
b, machine 2 } both machines
c, machine 1 } No amortisseur
d, machine 2 }

Curve A, No amortisseur, field resistance = 0
B, No amortisseur, field resistance considered
C, amortisseur, in machine 1—field resistance considered
C, amortisseur. In both machines, field resistance considered

$E_1 = E_2 = 1.0$, $\delta_{120} = 0$, $s = 0.02$

damping, equations 13 through 19 have been applied to a system with constants as shown in Table I.

First, with $E_1 = E_2 = 1.0$ and $\delta_{120} = 0$, equations 13 reduce to

$$D\Delta i_{d1} = -\omega(r_1 + r_2)\Delta\delta_{12}$$
$$D\Delta i_{q1} = [(\omega^2 + p^2)(x_{d1}(p) + x_{db}(p))]\Delta\delta_{12} \tag{20}$$

where

$$D = (\omega^2 + p^2)(x_{q1}(p) + x_{db}(p))(x_{q1}(p) + x_{q2}(p)) + r^2 + rp(x_{d1}(p) + x_{db}(p) + x_{q1}(p) + x_{q2}(p))$$

and

$$\Delta T_1 = \Delta i_{q1} \tag{21}$$

Figures 7 and 8 show the damping and synchronizing torque coefficients respectively calculated by equation 20 with $s = 0.02$ for the cases:

1. No amortisseurs, $r_{f1} = r_{f2} = 0$.
2. No amortisseurs, $r_{f1} = 0.00066$, $r_{f2} = 0.00033$.
3. Amortisseur in machine 1, $r_{f1} = 0.00066$, $r_{f2} = 0.00033$.
4. Amortisseurs in both machines, $r_{f1} = 0.00066$, $r_{f2} = 0.00033$.

Even with zero field resistances the damping torque is smaller in absolute magnitude than that of curve C, Figure 1, since now the effect of saliency is included and the machine reactances are different. Field resistance increases the absolute magnitude of the damping torque very slightly, while amortisseur windings make the torque more positive. With an amortisseur in only one machine the damping torque is negative for a very narrow speed band (approximately $0.027 < \omega < 0.034$), so that if the machines are accelerating from zero speed they may not have sufficient time to drop out of step in the interval required to pass through this band. It should, of course, also be remembered that the equations used do not apply strictly when the machines are accelerating, as a constant average synchronous speed has been assumed.

A few points calculated for a load angle of $\delta_{120} = -30°$ and $\Delta\theta_2 = -0.5\ \Delta\theta_1$ also are shown on Figures 7 and 8. This load angle reduces the damping torques of both machines, when both have amortisseurs.

Conclusions

As a result of this study it seems necessary to have amortisseurs at least as effective as those considered in Figure 7 on both motor and generator, if negative damping during the starting period is to be surely prevented.

If the system is accelerating it may, of course, not be necessary to have positive damping at all speeds, as the two machines may stay in step for a sufficient length of time even with some negative damping.

Symmetrical Short Circuits on Saturated Alternators

SAAD L. MIKHAIL
ASSOCIATE AIEE

THE investigation of the performance of the synchronous machine under transient conditions initiated by sudden short circuits is not a new problem. For the unsaturated machine, the problem was first investigated by Punga[1] in 1906, followed by a number of authors. Karapetoff[2] and Doherty and Nickle[3] give an excellent bibliography of the subject up to 1930. Since then several applications and extensions of Park's theory[4] have appeared.

On the other hand, the study of the saturated machine under steady-state conditions was under way. The saturation in the direct-axis was taken care of either by adding to the field excitation diagram, a saturation magnetomotive force obtained from a magnetization curve corresponding to the direct-axis current considered, as followed by Doherty and Nickle,[5] and by Robertson, Rogers and Dalziel,[6] or by the use of the no-load magnetization curve in conjunction with either Potier triangle[7,8] or Rüdenberg lines.[9–12]

However, as far as short-circuit transients on the saturated machine and with the exception of the contributions of Rüdenberg,[9–12] the literature has been satisfied with the shading of the unsaturated machine constants with empirical coefficients such as given by Wright[13] and Kilgore.[14] Rüdenberg's method consists in extending the construction used for the treatment of the steady-state direct-axis loading of the saturated machine, to give the symmetrical component of the current in the saturated machine under transients arising from switching of direct-axis loads.

It is the object of this paper to present the complete solution to the transients occurring in a saturated salient-pole synchronous machine due to a sudden 3-phase short circuit through an external inductance. The solution for a terminal short circuit is obtained by setting the value of the external inductance equal to zero. The case considered will be that with a constant excitation voltage and with the short circuit occurring from no-load. The machine will be assumed to have only one rotor circuit, namely, the field winding.

Starting with Park's equations,[4] and with the differential equation of the field winding, the classical method for their solution will be used. Obtained first will be the free transient which is the solution of the differential equations after the omission of all the stimulants in the circuits which in this case is the exciter voltage. Secondly, integration constants are evaluated from initial conditions; among which the initial current is evaluated using the principle of conservation of flux linkage in the field winding as used first by Doherty and Shirley,[15] and which is analogous to the principle of conservation of momentum in mechanical impact problems. Thirdly, the particular solution is obtained using Rüdenberg's method of analysis.[9–12] The theoretical results obtained are confirmed with test results.

Assumptions

With the exception of negligible saturation, the assumptions that will be made are essentially the usual assumptions made by previous authors:

1. Small stator and rotor resistances will be assumed.
2. The flux in the air-gap will be assumed the same as that effective in producing saturation in the armature.
3. The actual rotor leakage will be represented by an effective rotor leakage flowing only between pole tips.
4. The saturation in the armature after the short circuit is assumed to be negligible, and the change of degree of saturation from before to after the short circuit is assumed to be instantaneous.
5. The field time constant will be assumed much greater than the armature time constant; an assumption which is justified in big machines.

System of Notation

A nonreciprocal system of notation similar to that used by Doherty and Nickle[5] and by Park,[4] will be used. The units for magnetomotive force, flux, and reluctance will be different as they will be defined according to the field circuit. Table I gives the definitions for the various units used and their values for the machine tested.

Before attacking the main problem the subsequent definitions and relations will be introduced.

Equivalence Factor Between Rotor and Stator Currents

The equivalence factor γ between rotor and stator currents will be defined as the ratio of rotor to stator currents

Paper 50-253, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 20, 1950; made available for printing September 5, 1950.

SAAD L. MIKHAIL is Assistant Lecturer with Faroukh I University, Alexandria, Egypt, and now is on leave at Harvard University, Cambridge, Mass.

This paper is based upon a research project now being carried on by the author at Harvard University and supervised by Professor Reinhold Rüdenberg.

The author wishes to express his sincere gratitude to Professor Reinhold Rüdenberg of Harvard University for suggesting the study of the problem, for supervising the work and for many important contributions. He also is indebted to Professor C. L. Dawes and R. T. Gibbs of Harvard University for valuable help and interest. Credit is also given to F. Grotjohan and H. Baxter for their outstanding work in the manufacture of the necessary equipment and to the General Electric Company for supplying the requested design data for the machine tested. The author owes a great deal to the class notes on electrical machinery given by Professor C. A. Keener, of the University of Illinois and to his encouragement and interest.

Table I. Per-Unit System Used

Quantity	Unit	Value Corresponding to Machine Tested
Armature voltage	Normal phase voltage	120 volts
Armature current	Normal phase current	283 amperes
Armature impedance	Normal impedance	0.424 ohm
Speed	Normal speed	1,200 rpm
Frequency	Normal frequency	60 cycles
Electrical angular velocity	Normal electrical angular velocity	377 radians/second
Time	Time required for one electrical radian at unit frequency	1/377 second
Armature flux linkage	Armature flux linkage that when changes at unit rate produces unit voltage	0.318 volt sec
Field current	Field current corresponding to unit armature voltage of the air-gap line	3.946 amperes
Field impedance	Resistance of the field winding at the temperature of the test	8.46 ohms
Field voltage	Voltage necessary to drive unit field current through unit field impedance	33.382 volts
Flux	Total air-gap flux produced by the field winding, whose fundamental produces unit voltage at unit speed	1.96 megalines
Magnetomotive force	Field magnetomotive force per pole corresponding to unit field current	1,425 ampere turns
Reluctance	Reluctance that if a unit flux passes through it, the magnetic potential across it will be unit magnetomotive force	726 ampere turns/megaline
Field flux linkage	No-load field flux linkage	7.75 volt sec

that if each was acting alone, the same area for the air-gap flux density curve will be produced in each case.

However, if these two currents were acting simultaneously with their magnetomotive forces in opposition, the resultant air-gap flux density curve (Figure 8E), will have zero average value by definition, yet its fundamental will have a value. Since linkage with the field winding is proportional to the average value of the flux density wave, while linkage with the armature is proportional to its fundamental, such flux as of Figure 8(E), is a flux that links the armature and leaks with respect to the field, and thus it could be counted as an armature leakage flux. This flux will be called the difference leakage flux to distinguish it from the differential leakage flux, a term already used for the harmonic leakage flux.[18] The value of the armature linkage due to the difference flux produced by unit armature current is defined as the difference reactance and will be given the symbol x_Δ. In Appendix I, the value of x_Δ will be derived.

Armature Leakage Reactance

A definition for the armature leakage reactance has been given previously by Doherty and Nickle[5] and followed by Alger[16] and Kilgore[17] in its calculation and by March and Crary[18] and by Rogers[19] in its measurement. This definition being that the armature leakage reactance is the difference between the synchronous reactance and the armature reaction reactance in either the direct- or quadrature-axis. The armature reaction reactance being defined as that due to the space fundamental of armature magnetomotive force. This definition is a very useful one especially in the calculation of the machine constants. However, it is evident that it is not the only possible one, and a different definition will be used here. To the previous definition x_l, will be added the difference reactance x_Δ and the sum will be called the stator leakage reactance x_s, thus:

$$x_s = x_l + x_\Delta \tag{1}$$

It was advisable to use this definition, since dealing with saturation and with field flux linkage, the field magnetic circuit is affected by the average value of the air-gap flux density wave rather than by its fundamental.

Figure 1. An equivalent circuit for direct-axis transient reactance

Evaluation of the Equivalence Factor γ

Let the machine be considered under the condition of a 3-phase short circuit, the rotor and stator currents being I and i respectively. Thus through the main magnetic circuit of the machine is acting a magnetomotive force of $I-\gamma i$ which drives a flux of ix_s through the air-gap; the iron being unsaturated, thus:

$$I-\gamma i = ix_s \tag{2}$$

Figure 2. The main magnetic circuit of the machine when a direct-axis current is fed to the armature with the field winding short circuited

but

$$I = ix_d \tag{3}$$

from equations 2 and 3:

$$\gamma = x_d - x_s \tag{4}$$

$$= x_{sd} \tag{5}$$

where x_{sd} is the excess of the unsaturated direct-axis synchronous reactance over the stator leakage reactance.

Transient Reactance of the Unsaturated Machine

If a direct-axis current is supplied to the armature, with the field short circuited on itself, the reactance seen from the armature is the direct-axis transient reactance x_d'. This is generally decomposed into armature leakage reactance x_l and an effective field leakage reactance x_f'. Having used a different definition for the armature leakage reactance, x_d' will be decomposed into stator leakage reactance x_s and an effective rotor leakage reactance x_r', thus:

$$x_d' = x_s + x_r' \tag{6}$$

x_r' is then decomposed into x_{sd} in parallel with the rotor leakage reactance x_r. In

Figure 3. The main magnetic circuit of the machine at no-load

Figure 4. The main magnetic circuit of the machine after the occurrence of the short circuit

Figure 1, is shown the equivalent circuit for x_d' just described. It is obvious that:

$$x_r' = \frac{x_r x_{sd}}{x_r + x_{sd}} \tag{7}$$

In Figure 2 is shown the main magnetic circuit of the unsaturated machine with direct-axis current fed to the armature while the field winding being short circuited. The magnetomotive force of the armature is $i_d x_{sd}$; the total flux is $i_d x_d'$, the part $i_d x_r$ is a stator leakage and only $i_d x_r'$ crosses the air-gap. However, no part of it can link the field winding since it is short circuited on itself with an induced current I in it to drive all the flux $i_d x_r'$ in the rotor leakage paths.

Writing the circuital law equation for the outer circuit of Figure 2, there is:

$$i_d x_{sd} - I = i_d x_r' \tag{8}$$

or

$$I = i_d(x_d - x_d') \tag{9}$$

Writing the circuital law equation for the upper circuit of Figure 2, there is:

$$i_d x_{sd} = i_d x_r'(1 + R_l) \tag{10}$$

or

$$R_l = \frac{x_{sd}}{x_r'} - 1 \tag{11}$$

From equations (7) and (11); there is:

$$R_l = \frac{x_{sd}}{x_r} \tag{12}$$

Relation Between Per-Unit Pole Flux ϕ_p and Per-Unit Field Linkage Ψ

A linear relation always exists between Ψ and ϕ_p whether the machine is saturated or not, thus this relation will be obtained for the unsaturated machine and the results will be used for the saturated machine. In Figure 3 is shown the main magnetic circuit of the machine at no-load. Since the machine is unsaturated, then $R_a = 1$ and $R_p = 0$. Taking $\phi_a = 1$, thus:

$$\phi_l = 1/R_l \tag{13}$$

and

$$\phi_p = \phi_a + \phi_l = 1 + 1/R_l \tag{14}$$

This corresponds to unit flux linkage Ψ, thus:

$$\Psi = \frac{R_l}{R_l + 1}\phi_p \tag{15}$$

Substituting equations 7 and 12 in equation 16, there is:

$$\Psi = \phi_p \frac{x_r'}{x_r} \tag{16}$$

Having derived the necessary relations, the main problem now will be treated.

Differential Equations of the Machine

In order to solve the short-circuit problem, any investigator has to start by writing the differential equations in one form or another for each closed winding either on the stator or on the rotor. Any of these differential equations is of the form, $e = p\psi - ir$, where e is the terminal voltage, $p = d/dt$, ψ is the flux linking the winding, r is its resistance and i is the current through it considered positive when flowing from the induced to the terminal voltage. The solution of all these differential equations under the specified initial conditions gives the desired result. However, the difficulty in their solution arises from their nonlinearity. In fact there exist here two kinds of nonlinearity. The first is due to the change of coupling coefficients between the different windings due to the rotation of the rotor.

This nonlinearity could be removed by using the transform from phase to direct and quadrature components as used previously by Park.[4] The second nonlinearity is due to the saturation in the magnetic circuits and this nonlinearity could be treated by separating the solution into a free transient which meets linear though not unsaturated conditions, and a particular solution which meets saturated conditions and could be obtained by Rüdenberg's method.[9–13] The initial current being obtained by the principle of conservation of flux linkage in the field winding.[15]

Park's Equations

The differential equations of the stator windings as transformed to direct, quadrature, and zero components, has been used previously by Park[4] as:

$$e_d = p\psi_d - ri_d - \psi_q p\theta \tag{17}$$

$$e_q = p\psi_q - ri_q + \psi_d p\theta \tag{18}$$

$$e_0 = p\psi_0 - ri_0 \tag{19}$$

The differential equation for the field winding, using the opposite convention for the sign of the current is:

$$E = T_0 p\Psi + I \tag{20}$$

Figure 5(A) (below). Relation between pole reluctance R_p and particular solution for field flux linkage $_p\Psi$

Figure 5(B) (right). Relation between the rotor leakage saturation factor k, and the particular solution for the direct-axis current $_pi_d$

Equations 17 to 20 are applicable to both the saturated and the unsaturated machines and their solutions give the desired result. Since in a 3-phase short circuit, $i_0=0$, equation 19 will be omitted.

The Free Solution

As in the case of simple transients solved by the classical method, the complementary function gives the free transient. Thus if the stimulant E is omitted, the problem reduces to a machine having its field winding short circuited, running at synchronous speed, and carrying an armature current through an external inductance. In this case:

$$_f\psi_{ds}=-{}_fi_d(x_{ds}'+x_a) \tag{21}$$

and

$$_f\psi_{qs}=-{}_fi_q(x_{qs}'+x_a) \tag{22}$$

where the left-hand subscript f indicates the free solution, the subscript s indicates the saturated value and the subscript t indicates the totalized quantity of the machine and the load. The values of x_{ds}' and x_{qs} will remain constant all through the duration of the free transient. The reason for this will now be explained. Having assumed that the field time constant is much bigger than the armature time constant, the field leakage due to the particular solution keeps the pole tips very highly saturated, so that they are on the upper linear part of their characteristic all through the small duration of the free transient. Flux paths for the free solution involve the unsaturated armature, the very highly saturated pole tips and air paths; thus it is justifiable to write the linear though not unsaturated relations 21 and 22. The values of x_{ds}' and x_{qs}' will be discussed later.

Substituting equations 21 and 22 in equations 17 and 18 and using totalized values for the terminal voltage, flux linkage, and the resistance, and putting $e_{dt}=0=e_{qt}$, the condition for a symmetrical short circuit after the external reactance, there is:

$$0=-[r_t+p(x_{ds}'+x_a)]{}_fi_d+(x_{qs}'+x_a){}_fi_q \tag{23}$$

and

$$0=(x_{ds}'+x_a){}_fi_d+[r_t+p(x_{qs}'+x_a)]{}_fi_q \tag{24}$$

Equations 23 and 24 are two simultaneous equations in ${}_fi_d$ and ${}_fi_q$. Eliminating ${}_fi_d$, there is:

$$0=\left[p^2+r_t\left(\frac{1}{x_{ds}'+x_a}+\frac{1}{x_{qs}'+x_a}\right)p+1+\frac{r_t^2}{(x_{ds}'+x_a)(x_{qs}'+x_a)}\right]{}_fi_q \tag{25}$$

This is a second order differential

Nomenclature

All quantities are in the per-unit system given in Table I.

e = stator phase voltage
e_d,e_q,e_0 = direct, quadrature, and zero components of stator phase voltages respectively
E = field voltage
i = stator phase current
i_a,i_b,i_c = currents of phases a, b, c respectively
i_d,i_q,i_0 = direct, quadrature, and zero components of stator phase currents respectively
I = field current
r = armature resistance
x_d = unsaturated direct-axis synchronous reactance
x_{ad} = unsaturated armature reaction reactance
x_l = armature leakage reactance defined by Doherty and Nickle[5]
x_Δ = difference reactance derived in Appendix I
$x_s=x_l+x_\Delta$ a stator leakage reactance
$x_{sd}=x_d-x_s$
x_d' = unsaturated direct-axis transient reactance
$x_f'=x_d'-x_l$ effective field leakage reactance
$x_f=\frac{x_{ad}x_f'}{x_{ad}-x_f'}$ field leakage reactance
$x_r'=x_d'-x_s$ effective rotor leakage reactance
$x_r=\frac{x_{sd}x_r'}{x_{sd}-x_r'}$ rotor leakage reactance
x_b = armature leakage reactance with the rotor removed
$\alpha=x_r/x_{sd}$
x_{ds}' = saturated direct-axis transient reactance offered to the free transient
X_{ds}' = saturated direct-axis transient reactance offered to the particular solution
x_q = unsaturated quadrature-axis synchronous reactance
x_{qs}' = saturated quadrature-axis transient reactance
x_a = external reactance
T_{ds} = saturated armature time constant whose totalized value is given by equation 27
T_0 = unsaturated open-circuit field time constant
T' = unsaturated short circuit time constant of the field given by equation 50 B
$M_{\Delta\Delta}$ = magnetic potential across the armature and the air-gap
ϕ_a,ϕ_l,ϕ_p = fluxes in the armature, rotor leakage paths, and pole body respectively
R_a,R_l,R_p = reluctances of the armature and the air gap, that of the rotor leakage paths, and that of the pole body respectively
k = saturation factor for the rotor leakage paths at any instant and is greater than 1.
k_1 = value of k immediately after the occurrence of the short circuit
$B_1,B_{an},B_{ln},B_{11},C_1,C_{ln},C_p,C_{p1}$ = defined in Appendix 1
ψ_d,ψ_q,ψ_0 = direct, quadrature, and zero components of armature phase flux linkages respectively
Ψ = field flux linkage
ν = frequency of free transient given by equation 28
θ = angle by which the direct-axis leads the axis of phase a at any time
θ_0 = value of θ at the time of occurrence of the short circuit
$p=d/dt$
t = time
"t" added to the subscripts of a quantity indicates the totalized quantity of the machine and the external load.

Figure 5(C) (left). Relation between the particular solutions for field flux linkage $_p\Psi$ and direct-axis current $_pi_d$

Figure 5(D) (right). Relation between rotor leakage saturation factor k, and the particular solution for field flux linkage $_p\Psi$

Figure 5(E)(left), Figure 5(F)(right). Graphical solution of equation 51

equation whose solution is:

$$_f i_q = A\epsilon^{-t/T_{a1s}} \sin(\nu t+\beta) \tag{26}$$

where

$$T_{a1s} = \frac{2(x_{ds}'+x_a)(x_{qs}'+x_a)}{r_1[(x_{ds}'+x_a)+(x_{qs}'+x_a)]} \tag{27}$$

and

$$\nu^2 = 1+\frac{r_1^2}{(x_{ds}'+x_a)(x_{qs}'+x_a)} - \frac{1}{T_{a1s}^2} \tag{28}$$

and where A and β are integration constants.

The assumption of small resistance in the armature circuit allows ν to be taken equal to unity. Also at time $t=0$, $_f i_q = A \sin \beta$. Since the short circuit is occurring from no-load, this value must be equal to minus the value at time equal to zero of the particular solution of i_q which will be shown afterwards to be equal to zero, thus $\beta=0$, giving:

$$_f i_q = A\epsilon^{-t/T_{a1s}} \sin t \tag{29}$$

The value of A will be evaluated later.

Substituting equation 29 in either equations 23 or 24, and keeping in mind the assumption of small totalized armature resistance, the free solution for i_d is given by:

$$_f i_d = -A\left(\frac{x_{qs}'+x_a}{x_d'+x_a}\right)\epsilon^{-t/T_{a1s}} \cos t \tag{30}$$

whose value at time equal to zero is

$$-A\left(\frac{x_{qs}'+x_a}{x_{ds}'+x_a}\right)$$

This must be equal to minus the value at time equal to zero of the particular solution. The latter will be defined as equal to e/X_{d1s}', where X_{d1s}', is the totalized transient reactance and whose value will soon be derived. From the above discussion, the value of A is given by:

$$A = \frac{e}{X_{d1s}'}\left(\frac{x_{ds}'+x_a}{x_{qs}'+x_a}\right) \tag{31}$$

Thus the free solutions of the direct and quadrature currents are given by:

$$_f i_d = -\frac{e}{X_{d1s}'}\epsilon^{-t/T_{a1s}} \cos t \tag{32}$$

and

$$_f i_q = \frac{e}{X_{d1s}'}\frac{x_{ds}'+x_a}{x_{qs}'+x_a}\epsilon^{-t/T_{a1s}} \sin t \tag{33}$$

Substituting equations 32 and 33 in equations 13 of Park's paper,[4] and setting $\theta=\theta_0+t$, the free solution for the phase currents is given by:

$$_f i_a = -\frac{e}{2X_{d1s}'}\epsilon^{-t/T_{a1s}} \times \left[\frac{(x_{ds}'+x_a)+(x_{qs}'+x_a)}{x_{qs}'+x_a}\cos\theta_0 + \frac{x_{qs}'-x_{ds}'}{x_{qs}'+x_a}\cos(2t+\theta_0)\right] \tag{34}$$

Figure 5(G). Particular solution of the field flux linkage $_f\Psi$

For a terminal short circuit, putting $x_a=0$ and replacing X_{d1s}' by X_{ds}', the free solution for i_a is then given by:

$$_f i_a = -\frac{e}{2X_{ds}'}\epsilon^{-t/T_{a1s}}\left[\frac{x_{ds}'+x_{qs}'}{x_{qs}'}\cos\theta_0 + \frac{x_{qs}'-x_{ds}'}{x_{qs}'}\cos(2t+\theta_0)\right] \tag{34B}$$

Expression for $_f i_b$ could be obtained by replacing θ_0 by $\theta_0-2\pi/3$ in equations 34.

Expression for $_f i_c$ could be obtained by replacing θ_0 by $\theta_0+2\pi/3$ in equations 34.

The free solution for the field current could be obtained by substituting equation 32 in equation 9 and replacing x_d' by x_{ds}', giving:

$$_f I = -\frac{e}{X_{d1s}'}(x_d-x_{ds}')\epsilon^{-t/T_{a1s}} \cos t \tag{35}$$

For a terminal short circuit, the free solution for the field current is given by:

$$_f I = -\frac{e}{X_{ds}'}(x_d-x_{ds}')\epsilon^{-t/T_{a1s}} \cos t \tag{35B}$$

Totalized Direct-Axis Saturated Transient Reactance X_{d1s}'

This reactance has been defined as the ratio of the voltage before the occurrence of the short circuit to the particular solution of the armature current immediately after its occurrence, and will be calculated by finding the flux linkage in the field winding at no-load, then after the short circuit and equating these two flux linkages thus utilizing the principle of conservation of flux linkage.[15]

To obtain the pole flux before the short circuit, reference is made to Figure 3.

$$\phi_a = e \tag{36}$$

and

$$\phi_1 = M_{AA}/R_1 = e\ R_a/R_1 \tag{37}$$

thus

$$\phi_p = \phi_a+\phi_1 = e(1+R_a/R_1) \tag{38}$$

After the occurrence of the short circuit, the magnetic circuit quantities may be represented as in Figure 4. The armature is now assumed unsaturated and thus $R_a=1$.

Referring to Figure 4, the following relations become evident:

$$_p\phi_a = {}_p i_d(x_l+x_a) \tag{39}$$

and

$$_p\phi_1 = {}_p M_{AA}/k_1R_1 = ({}_p i_d x_{ld} + {}_p\phi_a R_a)/k_1R_1 = {}_p i_d(x_d+x_l)/k_1R_1 \tag{40}$$

Figure 5(H). Particular solution for the direct-axis current $_pi_d$

Figure 5(I). Particular solution for the field current $_pi$

thus

$$_p\phi_p = \phi_a + \phi_1 = {}_pi_d\left[x_s + \frac{x_d}{k_1R_1} + x_e(1+1/k_1R_1)\right] \quad (41)$$

where the left-hand subscript p indicates the particular solution of the quantity.

Let $_pi_d(0)$ be the value of the particular solution of i_d immediately after the occurrence of the short circuit. By the principle of conservation of flux linkage, and since the free transient does not produce any field flux linkage at any time during its whole duration, and since the field flux linkage is proportional to the pole flux, equations 38 and 41 are equated, and substituting for R_1 from equation 12, there is:

$$X_{ds}' = \frac{e}{_pi_d(0)} = (x_s + x_e)\frac{1+\alpha/k_1}{1+\alpha R_a} + x_r'\frac{1}{k_1}\times\left(\frac{1+\alpha}{1+\alpha R_a}\right) \quad (42)$$

Where $\alpha = x_r/x_{1d}$ and where R_a is the reluctance of the armature and the air-gap before the occurrence of the short circuit.

For a terminal short circuit, substituting $x_e = 0$, there is:

$$X_{ds}' = x_s\frac{1+\alpha/k_1}{1+\alpha R_a} + x_r'\frac{1}{k_1}\left(\frac{1+\alpha}{1+\alpha R_a}\right) \quad (42B)$$

Equations 42 and 42B show two important points, the first is that the saturation of the pole body plays no role in the determination of the initial short-circuit current.

The second point is that although the stator leakage reactance x_s or the external reactance x_e do not saturate, yet their sum appears multiplied by a saturation factor. This is because although they do not saturate, yet the voltage behind their sum, constitutes a part of the magnetic potential that stimulates field leakage through the saturated pole tips. The appearance of the saturation of the armature in the expression is because it influences the field leakage before the short circuit which is a part of the flux linking the field winding then.

Values of x_{ds}' and x_{qs}'

x_{ds}' is the reactance offered to a direct-axis armature current when the field winding is short circuited and when the pole tips are saturated. Its value is thus given by:

$$x_{ds}' = x_s + \frac{1}{k_1}x_r' \quad (43)$$

The value of x_{qs}' varies from the unsaturated quadrature-axis synchronous reactance x_q when the machine is unsaturated to the reactance of the armature with the rotor removed x_{lb} when the machine is very highly saturated. The exact variation between these two limits will not be discussed here, and only an intermediate value will be taken. The value of x_{lb} could be calculated as shown by Schenkel.[20]

The Particular Solution

In order that the solution of the differential equations may be complete, to equations 32, 33, and 35, must be added any other solution due to the introduction of the stimulant E, previously omitted.

Since the resistance in the armature circuit has been assumed small, hence the steady-state armature current is a direct-axis current, implying that $_pi_q(\infty) = 0$, and hence, i_q is a current whose steady-state value vanishes, and thus its complete solution is the free transient, and only i_d and I have particular solutions.

Rüdenberg's Method

The particular solution for i_d and I, has been given previously by Rüdenberg.[9–12] Rüdenberg's method now will be rewritten, slightly modified.

The pole flux at any instant is given by equation 41. Substituting equation 12 in

Figure 6(A)(left). Free solution for the current, $_fi_{a1}$, in phase a

Figure 6(B) right. Free solution for the field current $_fi$

equation 41, there is:

$$_{s}\phi_{p} = {}_{s}i_{d}\left[\frac{x_r}{x_r'}x_d' - (1-1/k)\alpha x_d + x_s(1+\alpha/k)\right] \tag{44}$$

Substituting equation 16 in equation 45, there is:

$$_{p}\Psi = {}_{s}i_{d}\left[x_d' - (1-1/k)\frac{x_d}{x_{sd}}x_r' + x_s\frac{1+\alpha/k}{1+\alpha}\right] \tag{45}$$

Writing the circuital law equation for the outer circuit of Figure 4, there is:

$$_{p}I = {}_{s}i_{d}(x_d + x_s + {}_{s}\phi_{p}R_p) \tag{46}$$

Substituting equation 44 in equation 46, there is:

$$_{p}I = {}_{s}i_{d}\left[x_d + x_s + R_p\left\{\frac{x_r}{x_r'}x_d' - (1-1/k)\alpha x_d + x_s(1+\alpha/k)\right\}\right] \tag{47}$$

Substituting equations 46 and 47 in equation 20, there is:

$$E = T_0 p_p \Psi + {}_{p}\Psi \times \frac{x_d + x_s + R_p\left[\frac{x_r}{x_r'}x_d' - (1-1/k)\alpha x_d + x_s(1+\alpha/k)\right]}{x_d' + x_s - (1-1/k)\frac{x_d}{x_{sd}}x_r' - x_s\frac{(1-1/k)\alpha}{1+\alpha}} \tag{48}$$

or

$$E\frac{x_d'+x_s}{x_d+x_s} = T_t' p_p \Psi + {}_{p}\Psi \times \frac{1 + R_p\left[\frac{x_r}{x_r'}\frac{x_d'}{x_d+x_s} - (1-1/k)\alpha \times \frac{x_d}{x_d+x_s} + \frac{x_s}{x_d+x_s}(1+\alpha/k)\right]}{1-(1-1/k)\frac{x_d}{x_{sd}}\frac{x_r'}{x_d'+x_s} - \frac{x_s(1-1/k)\alpha}{(x_d'+x_s)(1+\alpha)}} \tag{49}$$

where

$$T_t' = T_0\frac{x_d'+x_s}{x_d+x_s} \tag{50}$$

Equation 49 can be written as:

$$-T_t' p_p \Psi = f({}_{p}\Psi) - E\left(\frac{x_d'+x_s}{x_d+x_s}\right) = \Delta, \tag{51}$$

Figure 5(E)

$f({}_{p}\Psi)$ could be plotted against ${}_{p}\Psi$ without much difficulty, since the relation between $f({}_{p}\Psi)$ and ${}_{p}\Psi$ contains constants of the machine, R_p and k. R_p is directly related to ${}_{p}\Psi$ from the magnetization curve of the poles as in Figure 5(A); k is related to the magnetic potential across the pole tips, that is, to ${}_{s}i_d\ (x_d+x_s)$ and consequently to ${}_{s}i_d$. The method given by Kilgore[14] will be used for the determination of k as a function of ${}_{s}i_d$ and is shown in Figure 5(B). The relation between ${}_{p}\Psi$ and ${}_{s}i_d$ is given by equation 45, and can thus be represented by Figure 5(C). From Figure 5(B) and Figure 5(C), the relation between ${}_{p}\Psi$ and k can be obtained and is shown in Figure 5(D). From Figure 5(A), Figure 5(D), the constants of the machine, and equation 49, Figure 5(E) could be obtained giving Δ against ${}_{p}\Psi$. From which $1/\Delta$ against ${}_{p}\Psi$ could be obtained as in Figure 5(F).

Figure 7. Oscillogram showing phase currents, field current and voltage after a 3-phase short circuit through an external inductance of 0.095, and from a no-load voltage of 1.3

From equation 49, there is:

$$\int dt = -T_t' \int \frac{1}{\Delta} d_p\Psi \tag{52}$$

For any value of ${}_{p}\Psi$, the value of $\int 1/\Delta \cdot d_p\Psi$ could be obtained by graphical integration from Figure 5(F), and thus the variation of ${}_{p}\Psi$ with time could be obtained as in Figure 5(G). From Figure 5(G), and Figure 5(C), the variation of ${}_{s}i_d$ with time could be obtained as is shown in Figure 5(H). From equations 46 and 16, Figure 5(A), Figure 5(G), and Figure 5(H), the variation of ${}_{p}I$ with time could be obtained as in Figure 5(I).

To get the particular solution for a terminal short circuit, x_s is equated to zero in the foregoing analysis. Equation 49 then becomes:

$$E\frac{x_d'}{x_d} = T' p_p \Psi + {}_{p}\Psi \times \frac{1 + \left(\frac{x_r}{x_r'}\frac{x_d'}{x_d} - \alpha(1-1/k)\right)}{1-(1-1/k)\frac{x_d}{x_{sd}}\frac{x_r'}{x_d}} \tag{49B}$$

where

$$T' = T_0\frac{x_d'}{x_d} \tag{50B}$$

To obtain the particular solution of the phase currents, the solution for ${}_{s}i_d$ obtained in Figure 5(H) is substituted in equations 14 of Park's paper[4] giving:

$$_{s}i_a = {}_{s}i_d \cos(l+\theta_0) \tag{53}$$

$$_{s}i_b = {}_{s}i_d \cos(l+\theta_0-2\pi/3) \tag{54}$$

$$_{s}i_c = {}_{s}i_d \cos(l+\theta_0+2\pi/3) \tag{55}$$

which means that the particular solution of the phase currents is the symmetrical component of the total solution and is a 60-cycle wave modulated according to the solution for ${}_{s}i_d$. These par-

Figure 8. Derivation of difference reactance x_Δ

ticular solutions for the stator currents and that of the rotor current shown in Figure 5(I), together with the free solution obtained before in equations 34 and 35, constitute the complete solution of the problem.

Application and Test Results

Only final results will be given here, intermediate steps will be omitted to save space.

The machine tested is 100 horsepower, 208 volts, 283 amperes, 60 cycles, General Electric synchronous motor. The damper bars of the machine were taken out for the purpose of the experiment. The machine has the following constants:

$x_d=1.83$; $x_1=0.093$; $x_r=0.224$; $x_{ad}=1.606$; $x_d'=0.367$; $T_0=412$; $r_1=0.0599$; $x_q=1.056$; $x_{1b}=0.174$; $x_r'=0.143$; $x_r=0.157$; $\alpha=0.0978$

T_0 was determined oscillographically, the leakages were calculated, the rest of the constants were both calculated and measured giving differences of less than 3 per cent. With the exception of T_0, the foregoing values are the calculated values.

With the exception of the constants introduced in this paper, Kilgore's paper[17] was followed in the calculations of the constants.

The machine was short circuited at no-load at a voltage of 1.3, a field current of 2.38, and through an external reactance $x_e=0.095$ at $\theta_0=1.955$.

The Calculated Particular Solution

Figure 5(A) to 5(I) corresponds to this case. From Figure 5(D), $k_1=1.177$, thus

$$x_{ds}'=0.244+\frac{1}{1.177}0.143=0.346$$

$$X_{dis}'=(0.224+0.095)\frac{1+0.0978/1.177}{1+1.28\times0.0978}+0.143\times\frac{1}{1.177}\times\frac{1+0.0978}{1+1.28\times0.0978}=0.4255$$

Where 1.28 is the value of R_a before the short circuit, thus the initial symmetrical component of armature current is given by:

$${}_pi_d(0)=\frac{1.3}{0.4255}=3.05$$

In Figure 5, the method outlined before is applied to find the particular solution corresponding to this case and the particular solutions for i_a and I are shown in Figure 5(H) and 5(I) where they are compared with the tested results.

The Calculated Free Solution

No attempt was made to find the exact value of x_{qs}' and since the value of the second harmonic observed in the armature current was negligible, x_{qs}' was taken equal to x_{ds}' thus

$$T_{ds}'=\frac{0.346+0.095}{0.0599}=7.37$$

thus

$$_fi_a=-3.05(\cos 1.955)\epsilon^{-t/7.37}=1.14\epsilon^{-t/7.37}$$

and

$$_fI=3.05(1.83-0.346)\epsilon^{-t/7.37}\cos t=4.52\epsilon^{-t/7.37}\cos t$$

Comparison Between Calculated and Test Results

In Figure 7 is shown the oscillogram taken from the machine corresponding to this case. In Figure 5(H) is shown the envelope to the symmetrical component for i_a both calculated and tested results. In Figure 5(I), is shown the particular solution for the field current I, both calculated and tested. The deviation near zero time is due to assumption 4 that the drop of saturation in the armature is instantaneous; actually it decays approximately with the armature time constant. Otherwise the agreement between calculated and test results is within 4 per cent. In Figure 6(A) and 6(B) is shown the free solutions for i_a and I both calculated and measured. Since x_{qs} was not calculated but assumed on the basis of the oscillogram, and since the angle θ_0 was also estimated from the oscillogram, no real check could be claimed for the free solution.

In the oscillogram is observed that the field voltage is not constant but there is a small fluctuation which is due to the drop of the free solution of the field current through the inductance of the exciter armature. Since it is small and lasts for a small duration, it is ignored.

Appendix I. Evaluation of Difference Reactance X_Δ

Figure 8(A) gives the magnetomotive force distribution of maximum value M_f due to the field current only. Figure 8(B) gives the permeance distribution for the zero component of the magnetomotive force and to a different scale, the flux density distribution due to the magnetomotive force distribution of Figure 8(A). Let this flux density wave have a maximum value of M_fB_m, an average value of M_fB_{av} and a fundamental of M_fB_1.

Following Kilgore's nomenclature,[17] let:

$$C_1=B_1/B_m \tag{56}$$

and

$$C_p=B_{av}/B_m \tag{57}$$

In Figure 8(C), is shown the distribution of the space fundamental of magnetomotive force of unit magnitude due to stator currents. Neglecting the small variation of the permeance distribution from the zero harmonic of magnetomotive force to the fundamental,[4] the multiplication of Figures 8(B) and 8(C) gives the air-gap flux density distribution due to the stator magnetomotive force only and is given in Figure 8(D). Let the fundamental of Figure 8(D) be B_{11} and let C_{d1} and C_m be defined such that:

$$C_{d1}=C_1C_m=B_{11}/B_m \tag{58}$$

The condition for the definition of the difference reactance is that the curve of Figure 8(D) and that of Figure 8(B) have the same area. The difference between the former and the latter is the wave shown in Figure 8(E) which must have zero area, thus:

$$\frac{1}{2}C_1B_m=M_fC_pB_m \tag{59}$$

or

$$M_f=C_1/2C_p \tag{60}$$

The difference reactance, by definition is proportional to the fundamental of the curve of Figure 8(E), or to the difference between the fundamentals of Figures 8(D) and 8(B)

$$x_\Delta=\lambda(C_{d1}-C_1M_f) \tag{61}$$

Where λ is a constant of proportionality. Substituting equation 60 in equation 61, there is:

$$x_\Delta=\lambda(C_{d1}-C_1^2/2C_p) \tag{62}$$

But the armature reaction reactance x_{ad} is proportional to C_{d1}, thus:

$$x_{ad}=\lambda C_{d1} \tag{63}$$

Substituting equation 63 in equation 62 there is:

$$x_\Delta=x_{ad}(1-C_1/2C_mC_p) \tag{64}$$

No Discussion

An Experimental and Analytical Study of Turbine Generator Rotor Ventilation

CARL J. FECHHEIMER
FELLOW AIEE

THERE is no way known whereby the volume and pressure distribution of the gas flowing in the rotor of a completed turbine generator can be measured, nor can copper temperatures at selected points be measured readily. Surface temperatures taken after shutdown either by thermometer or contact thermocouple are none too good, owing to lapse of time, and they convey no information about localized copper temperatures. The only dependable method is temperature by resistance of the winding; this gives only the average temperature, and the engineer still lacks test data on copper temperature distribution. Recognizing the importance of the knowledge of the latter, the researches described herein were undertaken as a first step in the solution. It is still another step to calculate the temperature distribution of the steel and copper, after the ventilation pattern has been obtained. The Peck[1] and Soderberg[2] methods involve tedious calculations, and with the violent disturbances in the gas streams, the heat transfer coefficients should be determined from tests on models, if such data had not been obtained, before proceeding with the temperature calculations.

The experimental work described herein was undertaken some years ago at the Westinghouse Electric Corporation, but was not published. Experiments were made on a stationary as well as on a rotating model. The stationary model simulated the construction of a 4-pole plate rotor which was manufactured by them then; and the rotating model tests were made in combination with a model of part of a stator having the multiple path radial ventilation system.[3] As a few details of the two models differ from most present-day constructions, experiments on another relatively simple stationary model could be made; perhaps added tests on another rotating model, would not be needed.

Some of the experimental data and methods of approach and calculation may prove to be useful to engineers engaged in the design of gas-cooled turbine generators. So far as is known, nothing of a similar nature has been published. Also, there were some unexpected phenomena which may be of scientific interest to engineers engaged in fluid flow studies. No claim is made as to the means of calculation for a generator rotor being precise, and they are herewith presented as reasonably close approximations. The results from the rotating model may be helpful in a study of other rotor ventilation problems. Attention also is called to the application of the model experiments to an actual rotor and the plot of the results in Figure 13. The ventilation system studied is the one in which there are longitudinal ducts below the winding slots, and the gas emerges from radial ducts in the teeth. Inasmuch as engineers are familiar with that system, a schematic illustration is not included. The experiments were made with air, but the results can be applied readily to similar rotors cooled with hydrogen.

From the data secured from the stationary model, the volume* distribution was obtained, and discharge coefficients were evaluated. Such information, although valuable, was insufficient. From the rotating model the following were determined:

1. Pressure volume curves of the rotor acting as a fan, and their equations.
2. The influence of the axial components of the gas velocities in the air gap upon the gas that passed through the rotor vents.
3. The influence of the velocities of the gas streams from the stator vents discharging into the air gap, in the same, or not in the same plane as the rotor vents.

Data obtained from the stationary and the rotating models were then used in the calculation of an actual rotor's ventilation. Then the back pressure in the air gap arising from the stator ventilation is also allowed for.

The Stationary Model

The stationary model is shown in Figure 1, and is built of hardwood, in which one axial channel and 34 radial vents are reproduced. It simulated the full size vent system of one slot and tooth in half of a rotor whose body length would be 215 inches. A suitable centrifugal fan supplies air through a thermal volume meter whose inside sectional dimensions are $3^1/_2$ by $3^1/_2$ inches. There is comparatively little loss of head where the air turned a right angle corner before entering the axial channel in the model, as the velocities in those parts were low. The air then flowed through the 18-inch axial channel whose rectangular section is the same as the channel below the slots. This corresponds to the distance for flow through an end forging. One of the 34 blocks that followed is shown in detail at the left in Figure 1. Each block imitates a plate with a 3/8-inch radial vent at each plate. Soft rubber plugs could be driven into the outlets of the vents to close them as might be desired for a particular test.

* For simplicity, "volume" is used in this paper to denote the volume of gas flow per unit of time.

Paper 50-254, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 26, 1950; made available for printing August 31, 1950.

CARL J. FECHHEIMER is a consulting engineer, Milwaukee, Wis.

The author wishes to express his appreciation to the Westinghouse Electric Corporation for having given him the opportunity to conduct the research, and for permission to publish the results after a considerable lapse of time following the experiments. He also wishes to thank G. W. Penney and H. B. Holroyd, who assisted ably in the investigations.

Figure 1. Construction of stationary model

The brass tubes at the tops of the wedges are connected through rubber tubing to a manifold provided with a large number of cocks, one for each tube, and the manifold is connected to a manometer. The 1/16-inch diameter holes just below the wedges connect the tooth ducts with the holes into which the brass tubes have been driven. When an outlet is closed with a soft rubber plug, no air flows in that duct, and consequently only axial duct static pressure is read. When an outlet is open, and air flows in the vent, there is a loss of head from the bottom of the wedge to atmosphere, and its measurement affords the means of determining the volume of flow in the duct, when suitably calibrated. For calibration, the ducts before and after the one being calibrated are closed, they being used for pressure measurement. The pressure at the duct through which air flowed is taken to be the arithmetical mean of the pressures at the closed ducts.

A dimensionless coefficient is defined by:

$$C_d = \frac{P/\gamma}{V^2/2g} \qquad (1)$$

where V is the radial velocity in the tooth duct at its minimum section, g is the acceleration of gravity, P is the pressure, and γ is the fluid's weight density. P/γ is the head required to drive the air through the vent. (Wherever $V^2/2g$ is used for air having a density γ of 0.074 pound per cubic foot, it may be written as $(V/4030)^2$, and V is then in feet per minute, and P/γ is in inches of water column.) It was found that C_d is far from being a constant, but is dependent upon the axial duct velocity. Generally about the same values of C_d were obtained for given values of v/V (axial velocity/radial velocity). The axial velocity is taken just ahead of the radial duct. A plot of C_d for the average duct is shown in Figure 2.

No satisfactory explanation has been given for this curve's peculiar shape. The points around the hump were taken very close together and with great care, and there is no doubt regarding its existence. There is a much smaller hump at higher values, which was noticeable when plotted to a larger scale. Also, why is the range of values of C_d so large? Curves for C_d were taken for many ducts, and the points obtained were not always coincident. The model was then dismantled, and the areas at the minimum sections were measured, and were found to differ appreciably. A calibration was required for each duct. Tests made previously on a model for C_d for stator vents also showed a rise of C_d with axial duct velocities, but the high values were not so great as for the rotor ducts, and no hump was observed. This was pointed out in a previous paper.[8]

Distribution curves were subsequently taken with many radial ducts open. In Figure 3 are typical curves, with 24 radial vents open, the first eight, tenth, and last ducts being closed. The radial volumes were obtained from manometer readings of the pressure at the bottom of the wedges, in combination with the previously obtained calibrations, and from the measured minimum areas for individual ducts the radial velocities V were calculated. The axial volume is that from the volume meter readings minus the sum of the volumes discharged from previous radial ducts. This divided by the axial duct section gives the axial velocity v. Having v/V, C_d was read off of the duct's calibration curve. The static head in the axial duct, P/γ, was then calculated from equation 1. Values of $P/\gamma + v^2/2g$ are plotted in Figure 3. The general shape of the radial duct volume curve is somewhat similar to those found for turbostator and salient-pole alternator radial duct discharge. The volume in duct 33 is about 4.6 times that near the entrance.

The Rotating Model

For the rotating model, the parts that simulated the rotor were built of two plates, shown in Figure 4, there being but one vent duct axially. It was made one third the size of a 51-inch diameter rotor, the width of the vent being 0.125 inch instead of 0.375 inch. Metal bars were placed in the slots and wedges in the wedge grooves after assembling. Figure

Figure 2. Coefficients of discharge in a rotor vent duct, plate construction

Figure 3 (left). Stationary model test results

Figure 5 (right). Cross-section of rotating model

5 shows a cross-section and conveys a picture of the paths for air flow. Attention is called to the following:

1. The rotor, acting as a fan, caused air to flow from the atmosphere into the air gap (passages 1, 5, 4 and so forth), the volume being controlled by throttling in the stationary duct ahead of the entrance to the rotor.

2. A separate fan supplied air for axial flow in the air gap, entering the gap at 2.

3. Another separate fan supplied air for inward radial flow from the stator, entering the stator vents at 3.

4. The stator, provided with two vents, could be moved axially, so that tests could be made with the stator and rotor vents in line, and with the rotor vent midway between the stator vents.

By adjusting the speeds of the separate fans, their volumes were controlled. The effects were studied separately and in combination.

The labyrinth seal almost eliminated air leakage. However, tests were made with the aid of a vacuum cleaner fan which blew air into the clearance in the seal, with a rubber stopper closing the entrance to the rotor inlet, and the leakage volumes were measured with an orifice for various pressures. Allowances for leakages were made in subsequent tests, the corrected data only being given on the curve sheets.

The air volumes and pressures were measured as follows:

1. For the flow into the rotor, an orifice was placed in the intake pipe. A vacuum cleaner fan was placed in series so as to compensate for the drops in the orifice and pipes up to the rotor entrance. A thermal volume meter was used for calibration. A manometer connected to the entrance read the static head for the rotor air, below atmospheric pressure.

2. For the flow into the air gap, a manometer was connected to an impact tube placed at the entrance of the separate fan discharging into the air gap. After calibration with an impact tube held at the air gap, this afforded a means of measuring the air gap volume. This was sufficiently accurate, although not of the same degree as the other measurements.

3. For the flow to the stator vents an orifice was used. The pressure measured beyond the orifice was taken as the "stator pressure."

Notches were cut into the stator's surface adjacent to its inner periphery to imitate sunk stator slots. The stator was made of wood. The air gap in the model was 0.50 inch radially.

Results of Tests with the Rotating Model

In an actual machine most of the rotor pressures are positive, that is, above atmospheric pressure. In the model tests they were negative. Neglecting small differences due to departures in air density, the pressure volume curve should not be affected thereby.

Effect of Axial Flow in the Air Gap

Typical pressure-volume curves are like those in Figure 6. No air was supplied to the stator, and the fan for axial gap air was either stationary or driven at

Figure 4. The two plates of rotating model

Figure 6. Test pressure-volume curves with rotating model. Curves show influence of axial gap velocity

Conditions:
Rotor speed = 2,000 rpm
Stator vent duct velocity = 0
No vane to stop whirl

Figure 8 (right). Calculated pressure volume curves for rotating model. All curves are parabolas, and show influences of axial gap velocity

Conditions:
Rotor speed = 2,000 rpm
Stator vent duct velocity = 0

such speeds that the axial gap velocity was 3,300 or 5,500 feet per minute, the rotor running at constant speed of 2,000 rpm. The difference in pressures between any two curves is substantially constant for all values of volume. Thus, the effect of gap axial flow is to produce the equivalent of a constant pressure drop for a given axial gap velocity. Although this pressure difference is appreciable, the difference is small from 3,300 to 5,500 feet per minute. (The values of axial gap velocities should be taken as relative to the peripheral velocity, in this case 8,900 feet per minute.) An explanation is that the moving axial stream cleans off the rotor surface, thereby making the egress from the radial vents more difficult. After a particular relative gap velocity is attained, the surface is completely cleaned and further increase does not affect the rotor's volume or pressure. This is one of the unexpected phenomena.

In Figure 6 the curves bend upward for low values of volume. This was due to the effect of the passage 5 in Figure 5, acting as a fan just as any smooth rotating disk propels a fluid to some extent. A stationary vane was placed in that passage which almost eliminated the whirling of the air therein, which then became negligible, except for small volumes. A plot in Figure 7 is of tests made with and without the vane. The dotted curve is that of a parabola, which coincides substantially with the major and important part of the curve. In Figure 8 the curves are calculated parabolas for various axial gap velocities, the pressure differences between any two curves being independent of the volume.

Equation of the curves in Figure 8 is

$$P/\gamma = P_0/\gamma[1-(Q/Q_0)^2] \qquad (2)$$

P/γ is the entrance head at volume Q, (P_0/γ) is the rotor entrance head at zero volume, and Q_0 is the volume at zero pressure. For the calculated curve in Figure 7, which is the top curve in Figure 8, the equation is

$$P/\gamma = 2.63[1-(Q/_{26.6})^2]$$

For zero axial velocity in the air gap, and zero volumes in the stator and rotor vents,

$$P_0/\gamma = (U_2^2 - U_1^2)/2g \qquad (3)$$

where U_2 and U_1 are respectively the external and internal tangential velocities of the rotor vent, the latter being taken at the radius half way down the rotor axial duct. It was found that on that same curve the volume at zero pressure, Q_0, could also be calculated within a few per cent, the resistances to air flow having been estimated, and the assumption was made that all the generated head, P_0/γ, was consumed in resistance drop.

To allow for the effect of the axial velocity in the air gap, the curve in Figure 9 may be used. The fraction of peripheral velocity head $(U_2^2/2g)$ to deduct from the generated head is plotted against: (axial gap velocity)/(rotor peripheral velocity).

Effect of Gas Impinging from the Stator Vents

The air flowing radially inward from the stator vents creates disturbances in the air gap which make the egress of air from the rotor vents more difficult. In the lower part of Figure 10 the curves from tests are of the rotor net pressure for various stator pressures back of the core, with inward air flow, and zero axial flow in the gap. The six curves are straight lines, showing that the drop in rotor pressure due to the disturbance is proportional to the pressure drop through the stator vents. Thus, that drop is proportional to the square of the stator vent duct velocity. The parameters of the curves are rotor air volume and relative axial positions of the stator and rotor vents.

In the upper part of Figure 10 some of the data from the lower curves are replotted as pressure-volume curves, as in the lower curves the rotor volumes for two axial positions generally differed. Evidently, except for small rotor air volumes, the effect of axial position may be neglected, and even for small volumes, the effect is not great. Note that for these curves, the drop due to impinging air is independent of the rotor air volume, and is about 0.35 inch of water for 2.5 inches of water back of the stator core, corresponding to stator vent duct velocity (volume/minimum section) V_s of 9,350 feet per minute. This drop is approximately $0.065\ (V_s/4{,}030)^2$.

Stationary vane in entrance radial passage

Combined Effects

In Figure 11 the test curves show the influence of axial gap velocity and of inward flow from the stator vents. In Table I calculated and test pressures are compared for 14 cubic feet per minute.

Table I

Gap Velocity	Vent Velocity	Net Head Calc.	Net Head Test
0	0		1.88
0	8,150	1.62	1.60
0	9,550	1.52	1.47
5,200	10,100	0.94	0.98

Although no experiments were made to determine the influence of outward flow in the stator ducts upon the rotor pressure or volume, it seems evident that since little, if any, disturbance is produced in the air gap thereby, no allowance need be made. It is, of course, essential to deduct from the rotor pressure, the pressure in the air gap in addition to these deductions. It also seems that since the rotor volumes are small compared with those needed for stator cooling, the influence of the air flowing through the rotor vents upon the volumes and pressures for the stator may be neglected.

Figure 10. Rotating model test data. Influence of impinging streams from stator vents upon flow through rotor. Lower curves show influence of pressure back of stator core upon rotor pressure for several rotor gas volumes and for stator vents in same and different planes from rotor vents

Upper curves obtained from lower curves, and are pressure-volume curves for two stator pressures

Calculations for a Turbogenerator Rotor

The calculations are for a generator which was rated 62,500 kva, 60 cycles, 1,800 rpm. It had a plate rotor, and was built some years ago, before turbos were cooled with hydrogen, and before the advent of large 2-pole 60-cycle rotors. With internal centrifugal fans, there is a decrease in pressure in the region of the rotor end plates where the gas enters, and such pressure must then be deducted from the rotor generated pressure. Allowance for this negative pressure may be made with the aid of Figures 29 and 30, of the paper on Centrifugal Fans for Electrical Machinery.[4] With propeller fans, their delivered pressure should be added to the rotor generated pressure. For the example given, the pressure ahead of the holes in the end plate is taken as atmospheric pressure.

The ventilation of the stator was calculated, and plotted in Figure 12. This includes gap and radial vent velocities, and pressures in the air gap, for both inward and outward flow. The methods for these calculations are given in a previous paper.[3]

When there is atmospheric pressure at entrance, the general equation, from Bernoulli's theorem, is:

$$P_0/\gamma = 1/\gamma(P_g + P_{ax} + P_s) + v^2/2g + \Sigma \text{ losses} \quad (4)$$

where

P_0 = generated pressure from equation 3
P_g = gap back pressure from Figure 12
P_{ax} = drop due to axial flow in gap from Figures 9 and 12
P_s = drop due to impinging air from stator
$v^2/2g$ = velocity head in axial duct

Since C_d depends upon the velocities, and consequently upon the volume of gas flow, it is first necessary to estimate roughly that volume. P_0/γ from equation 3 was found to be 23.5 inches of water. From Figure 12, rough averages of P_g/γ and gap axial velocities are about 6.5 inches and 4,200 feet per minute respectively, the latter 0.162 times the rotor peripheral velocity. With the aid of Figure 9, $P_{ax}/\gamma = 1.7$ inches. P_s will be neglected in this first approximation.

The losses are:

1. Loss through the end plate holes of area A_b and contraction coefficient C_b.

2. Loss at entrance to the axial ducts of area $A_a = 1/2$ velocity head.

3. Loss due to friction drop. Assume for first approximation to be 1/2 velocity head.

4. Loss in the radial ducts from equation 1. For first approximation take C_d and V $(= Q/A_d)$ as constants, Q being the total volume from one end, and Ad the area at minimum section.

5. For $v^2/2g$, treat this as a loss also, and 1/2 velocity head.

Expressing all velocities as volume Q divided by the sectional area, and pressures in inches of water

$$Q = 4{,}030\sqrt{\frac{P_0 - P_g - P_{ax} - P_s}{\left(\frac{1}{A_b C_b}\right)^2 + \frac{1.5}{(A_a)^2} + \frac{C_d}{(A_d)^2}}} \quad (5)$$

Figure 12 (left). Velocities and pressures in stator and air gap in a turbine generator

Figure 13 (right). Calculated air velocities, net heads, and discharge coefficients in a turbine generator rotor

Gas volume in rotor body = 3,350 cubic feet per minute at each end

For $A_b = 1.04$, $A_a = 0.315$, $A_d = 0.68$ (all in square feet), and for $C_b = 0.80$, and $C_d = 1.80$, the numerical values of other quantities having been given previously, $Q = 3{,}450$ cubic feet per minute at each end.

For the second approximation this volume was used, and checked step by step, without the radical assumptions of the first approximation. The volume of 3,450 was found to be slightly high, as it did not give zero axial duct velocity at the middle of the rotor. As a third approximation, 3,350 cubic feet per minute was used, giving velocity at entrance to axial ducts of 10,620 feet per minute (see item 3, duct number 1, Table II). The air through the retaining ring vent holes of about 800 cubic feet per minute is added, giving 4,150 cubic feet per minute, as the air through the end plate holes.

The total drop up to the first radial vent is the sum of the following drops: end plate, 1.54 inches; entrance to axial ducts, 3.46 inches; friction drop through 18.875 inches of axial duct with coefficient of 0.0054, 2.48 inches; velocity head, 6.92, giving 14.40 inches of water drop, see item 4, duct number 1, Table II.

In Table II, results of calculations are entered for only three ducts. The drops are entered as pressures, P, and are given in inches of water. The methods for determining each quantity are given in the table. Items 11 and 12 were determined by cut and try, but it was not burdensome after a few attempts. Item 15 takes account of the gain in static head in the axial duct due to the abstraction of air in the radial duct, from which the loss of head due to reduction in axial velocity was deducted. For item 16 the coefficient of friction was taken to be the same throughout (0.0054), although it rises slightly with declining Reynolds numbers. (With small Reynolds numbers this loss is nearly negligible, because the velocity is low.)

There were a total of 21 ducts in the rotor, with number 11 at the center. Half of the air for that duct came from each end. There is a small residue of 198 cubic feet per minute, and had the chosen volume been just right, there would have been no residue. Considering that there are always some uncertainties in such calculations, it is not worthwhile to recalculate.

As a check on the arithmetic, the total volume is given by the sum of the volumes in the radial ducts, (item 13) plus the residue.

The results for one-half of the rotor are plotted in Figure 13. The axial velocity is shown as a stepped curve; the discharge at each radial duct decreases the velocity in the axial duct, and for simplicity, the axial velocity is shown as of constant value between adjacent radial ducts, since the shape of the curve over the width of, and adjacent to, a radial duct is unknown. The steps in the axial velocity curve do not change at a definite rate, as the discharges in the radial ducts change at an irregular rate. The radial duct velocity is 4,030 $\sqrt{\text{net head}/C_d}$, and both quantities under the radical change. They also are plotted in Figure 13, and should help to clarify the picture. The net head is item 10 in Table II, and is dependent upon the axial duct pressure minus the three drops in the air gap. In Figure 13 it appears as an irregular curve, and the radial duct velocity curve is of somewhat similar shape. The decrease in axial velocity from duct 10 to 11 would have been twice as great if there had been 22 ducts, and then no air for duct 11 would have come from the other end.

The unexpected phenomena which were observed in the experiments may be enumerated as follows:

1. The hump in the curve for C_d and the large increase with increasing ratios of axial to radial velocities, Figure 2.
2. The comparatively large decrease in ef-

The Goerges Phenomenon—Induction Motors with Unbalanced Rotor Impedances

HAROLD L. GARBARINO
ASSOCIATE AIEE

ERIC T. B. GROSS
FELLOW AIEE

Synopsis: The Goerges phenomenon is the operation of a 3-phase wound-rotor induction motor at half of synchronous speed, and it is obtained by unbalancing the rotor circuit. If the motor is started with one rotor phase opened or with rotor impedances greatly unbalanced, it will accelerate to half speed and operate stably as a motor or generator. Several investigators have made tests and analyses to find the characteristics of a motor operated in this way. In the present work a physical explanation and an equivalent circuit are given. Results of tests and calculations for a 5-horsepower motor are compared and found to be in good agreement. The unbalanced rotor impedances cause unbalanced rotor currents of slip frequency, and balanced stator currents of two frequencies, the fundamental and a subharmonic, the frequency of which depends on the speed. The motor may be operated stably at half or full speed. The torque at half speed is greater than at full speed, and may be almost as great as the rated torque for a balanced rotor. It may be desirable to operate an induction motor at half speed intermittently or as a temporary measure. Disadvantages of half speed operation are the low power factor, low pull-out torque, the subfrequency line currents, and motor vibrations.

THE induction motor with unbalanced rotor resistances was first studied by H. Goerges[1] more than 50 years ago. Since then several investigators have contributed to the knowledge of the subject with theoretical and experimental work. Early studies were concerned with one particular phase of the problem, namely, the 3-phase induction motor with a single-phase rotor. The operating characteristics of this machine are quite different from those of the motor with a balanced 3-phase rotor. The singular feature of operation with single-phase rotor is acceleration to only half synchronous speed upon starting, and stable operation in this speed region. The maximum torque for motor operation with this connection is greater at half speed than at full speed.

H. Goerges published[1] the first paper describing these characteristics in 1896, and others have since referred to the half-speed characteristic as "Goerges Phenomenon."[2,3] Goerges pointed out that at one-half of synchronous speed the motor torque is zero. In certain tests, the motor was used to operate a lift. At about half speed the motor was first used to raise the load, and then to act as a brake during the lowering of the load. Goerges stated that a 3-phase motor with a single-phase rotor could be operated at this reduced speed with less losses than the corresponding 3-phase rotor machine. He found that the efficiency for the single-phase connection was about 60 per cent at half speed, compared to 40 per cent for balanced 3-phase rotor at this same speed. Three-phase motors with single-phase rotors have been studied by others, and expressions derived for input current, torque, power, and other operating characteristics. Early studies were made in Europe,[4,5] in this country, B. G. Lamme[6] appears to be the first to have introduced the problem. Analyses, tests, and calculations based on an equivalent circuit confirmed some of the early observations of Goerges.

A problem closely related to that of the single-phase or unbalanced rotor is the starting from the line of a salient pole synchronous machine, or one with short-circuited field. With no damper winding this machine effectively has a single-phase rotor. When started, the machine may "crawl" at half speed.

A principal motive for the investigation of the unbalanced rotor circuit has been the search for a simple method of speed control. One important but inefficient method of speed control has been achieved by the use of variable resistances in the rotor circuit. Efficiency with this type of operation is reduced approximately in proportion to the speed; the electrical efficiency can never exceed the per cent speed at which the machine is operating. These resistances, which are also used for increasing starting torque and reducing starting current are often so constructed that they are unbalanced at many of the stepped positions at which they may be set. Studies were made to investigate the effect of this unbalance on input current, torque, and the losses in the motor. Gazda[7] and Jones[8] made tests to find the extent to which the rotor resistance may be unbalanced without deviating too much from normal performance. Other more recent contributions to the theory of the problem are contained in papers by Fourmarier,[9] Lyon,[10] Mauduit,[11] and Wagner and Evans.[12]

Analysis

An analytical approach to obtain a physical picture of the unbalanced rotor circuit phenomena, and to provide a basis for calculating the operating characteristics of such a machine, is based on the method of symmetrical components. This technique is suited for solving many 3-phase problems in which the electrical quantities are partially unbalanced. In

Manuscript submitted May 10, 1950; made available for printing August 31, 1950.

Harold L. Garbarino was Instructor in Electrical Engineering at the Illinois Institute of Technology when this investigation was made. He now is with the General Electric Company, Pittsfield, Mass. Eric T. B. Gross is Professor of Power System Engineering with the Illinois Institute of Technology, Chicago, Ill.

Figure 1. The induction motor with unbalanced rotor impedances

Figure 2. Complete equivalent circuit for two equal impedances in the rotor circuit

the problem at hand, the impedances of the three phases are the same, and the applied voltage is assumed balanced. The only unbalance is introduced by the connection of unbalanced resistances at the rotor slip rings. Resistance may be inserted between two phases, while leaving one line open, or resistances of different finite values may be inserted in all three phases, as shown in Figure 1. In this last case the characteristics of the motor approach those of the balanced rotor as the degree of unbalance is decreased. In symmetrical component analysis, the unbalanced quantities are resolved into balanced sets, and then treated separately in the calculations. This method has been the most common attack for the problem of the balanced 3-phase motor with unbalanced applied voltages which has been studied more frequently.

A description of the component motor fields which result in the unusual performance will be given here but for the derivation of equations for motor torque, losses, and currents, reference is made to previous authors.[12] It is well known that 3-phase voltages applied to the stator of a machine result in a magnetic field revolving at synchronous speed. When the rotor is at standstill, the field will induce voltages in the rotor of the same frequency as applied to the stator. When the rotor is rotating, the frequency of the induced rotor voltages and currents will depend on the relative velocity between the stator field and the speed of the rotor. This frequency will be greater if the rotor is rotating against the revolving field, and less if both are rotating in the same direction. The rotor quantities will be of a frequency equal to the product of the slip and the applied stator frequency (slip in per cent).

Any arrangement of unbalanced impedances connected externally in the rotor circuit, will cause unbalanced voltages of slip frequency to appear at the rotor terminals. These unbalanced voltages may be resolved into two symmetrical sets of phasors, the positive and negative sequence voltage components. Looking into the motor from the rotor terminals, the circuit will appear as a balanced network with unbalanced applied voltages, a problem of limited unbalance, and therefore suited for the application of symmetrical components.

The two symmetrical sets of rotor voltages and currents will be associated with two rotating fields revolving in opposite directions at slip speed with respect to the rotor, and may be arbitrarily identified as clockwise and counterclockwise. For the single-phase rotor, only a pulsating field will exist due to rotor currents, and this field may be resolved into equal components revolving in opposite directions. When the unbalance in the external circuit is small, the counterclockwise or negative sequence field will be rel-

Figure 3 (below). Equivalent circuit for the motor with single-phase rotor, or for two identical motors in concatenation

Figure 4 (right). Exact positive sequence stator current locus for single-phase rotor. External resistance, R is zero

atively small. If all speeds are taken as fractions of the synchronous speed, the per-unit slip is s, and the rotor speed is $(1-s)$, defined as moving in the clockwise direction. The rotor field then is moving with respect to the stator at a speed of s plus $(1-s)$, or at the same speed as the field set up by the balanced applied stator voltages. The applied voltages and positive sequence rotor terminal voltages, together with the appropriate impedances between, constitute the positive sequence network. Since this network is balanced, only one phase need be analyzed. The field arising from the negative sequence rotor terminal voltage rotates at a speed $(-s)$ with respect to the clockwise direction of the rotor, or at a speed $(-s)$ plus $(1-s)$ equal to $(1-2s)$ with respect to the stator. Therefore, this field will induce voltages of frequency $(1-2s)$ in the stator. The circuit for the currents of this frequency is through the impedances of the stator winding and the power lines supplying the induction motor. In general the impedance of the stator will be much greater than that of the power supply so that these currents may be considered as short circuited through the stator impedance with negligible error. An inspection of the frequency, $(1-2s)$, shows that it becomes zero for s equal 0.5, or at one-half of synchronous speed. Evidently, then, at this speed, the negative sequence rotor field is stationary with respect to the stator, and no current due to this component will flow in the stator.

The next question is: what are the directions of torque due to these component fields, and will the machine start? We may deduce a rule that a rotating field caused by stator currents produces torque in the same direction as that of field rotation, and that a rotating field caused by motor currents produces torque in the direction opposite to that of the rotating field. The torque in each case is in such direction as to decrease the relative speed of the rotating field and the conductors which it crosses on the opposite winding. The positive sequence circuit is similar to that of a balanced motor in the unbalanced machine, and will give a clockwise torque for most speeds. Considering next the negative sequence rotor field, it is apparent that at speeds less than half, the field is moving counterclockwise with respect to the stator conductors, and a clockwise torque is developed. Conversely, when the rotor is moving at greater than half speed, a counterclockwise torque is developed by the negative sequence component. For some conditions of unbalance the positive sequence torque will be counterclockwise at some speeds because of a change in the direction of positive sequence rotor currents, but over most speeds the torque will be clockwise. Therefore, the negative sequence torque will generally aid that of the positive up to half speed, and oppose it above half speed. At exactly synchronous speed, the relative velocity of the rotor and stator field is zero, and no rotor current will flow.

In a manner similar to that for the balanced induction motor, equivalent circuits can be derived for the positive and negative sequence networks of the machine with unbalanced rotor. Under certain conditions one complete network can be found, which will yield all sequence components of current in the machine. It is possible to connect the positive and negative sequence networks through a third network, representing the external rotor impedances, if two of the external impedances are equal. If this condition is not fulfilled, two equivalent circuits and in addition some relating equations must be used to solve the problem. An equivalent circuit for the conditions Z_b equal Z_c is shown in Figure 2. Here I_1 is the positive sequence stator

current of applied frequency, I_2 is the positive sequence rotor current of slip frequency, I_3 is the negative sequence rotor current of slip frequency, and I_4 is the negative sequence stator current of frequency $(1-2s)$. The impedances shown are the supply frequency equivalents which enable the actual values of component currents to be found for any rotor speed. Assumptions on which the circuit is based are: the impedances are constant, iron losses are negligible, and the electromagnetic fields are sinusoidally distributed in space. From the equivalent circuit the currents may first be found, and these then used to calculate the motor performance. For the single-phase rotor with zero external impedance between two rotor terminals, and with the third terminal open, the equivalent circuit reduces to that shown in Figure 3. It has been of interest to several writers[12] on the subject that this also is the equivalent circuit for two identical induction motors in concatenation, that is, connected in direct cascade, with the rotors connected together electrically and mechanically. In fact, Lamme calls the single-phase rotor a poor form of internal cascade, as compared to machines which are built with internal cascade connections for more flexible speed control.

Calculations and Tests

For calculation and test of an actual motor, a 5-horsepower 220-volt 8-pole 60-cycle wound rotor induction motor was used. The machine was rated at 18.2 amperes stator current and 845 rpm. Coupled to the motor was a d-c generator of about the same rating. Because of this it was impossible to conduct some desirable tests. By common test procedure the stator and rotor resistances and reactances, and the transformation ratio were found. The 60-cycle resistance was used as the stator resistance, although this is admittedly too high for the subfundamental frequency currents impressed from the rotor. For the rotor, the d-c resistance was used as the best approximation. Calculations were made of several electrical characteristics for the motor with single-phase rotor. One of these was the positive sequence stator current as shown in Figure 4, where the power component of current is in the direction of the abscissa, and the quadrature component in the direction of the ordinate. It is acting as a generator. Also calculated were the positive and negative sequence components and total torque as functions of speed, as shown in Figure 5, for the single-phase rotor. The maximum torque developed at approximately half-speed as generator is almost as great as the torque for the machine acting as motor, and these quantities are both greater than the maximum torque near the synchronous speed. Other calculated speed-torque characteristics are given in Figure 6, which shows the effect of inserting resistance between two rotor terminals. For an increase in resistance the torque curve tends to flatten out, and the dip near half speed becomes less until negative torque is no longer developed in this speed region. If the mechanical load on the motor is not too great, it will accelerate from standstill to speeds approaching synchronous.

Tests were made for several conditions of unbalanced external rotor resistance, and measurements taken of all electrical quantities, speed, and shaft torque. The applied motor voltage was about half of rated value, and the test results were corrected to values for rated voltage. Because of the small capacity of the coupled machine, it was impossible to make measurements in one unstable speed region, and characteristic curves in this region have been approximated. Four tests were performed on the motor with a single-phase rotor for different resistances between the two rotor phases. The resultant torque-speed characteristics are given in Figure 7. The value of torque in these curves is the total electrical torque, that is, the measured shaft torque plus the torque required to overcome friction and windage in the motor. This addition was made to give a better

Figure 7. Torque-speed characteristics obtained from tests of the single-phase rotor. (R is external equivalent resistance referred to stator)

comparison of test results with calculated electrical torque, although this component was at most 1.1 pound-feet.

Comparison of the test and calculated curves for zero external rotor resistance shows reasonable agreement. The torque at very low speeds was found to be higher than the calculated value, a result which was probably caused by a decrease of the leakage reactance with saturation at high currents.

Calculated efficiencies also agree fairly well with test results. Again from the test results, it is seen that the maximum negative torque in the half speed region decreases as the resistance is increased, and the positive torque at other speeds is decreased. If the motor is started with a sufficiently small load, and with enough resistance between the rotor terminals, it will accelerate past the half-speed region. When operating near synchronous speed, too high an increase in the load will cause the motor to lose stability, and slow down to the half-speed region, where the pull-out torque is higher. This maxmium torque at half speed is considerably less than the calculated maximum torque of the balanced motor, which is about 57 per cent higher than that of the single-phase rotor at half speed, and about 150 per cent higher than that of the single-phase rotor operating near synchronous speed.

Another series of tests was performed with a resistance inserted in one phase, and zero resistance in the other two, Figure 8. As expected, a reduction of resistance R causes the curve to approach the condition for balanced rotor. The curve for the single-phase rotor, or infinite resistance in one phase, is given again for comparison. Other tests were conducted with equal resistances in two phases and zero resistance in the third, Figure 9. The irregularity of the speed-torque curve is here less pronounced. An increase in the resistances decreases the torque near synchronous speed, and increases the torque at low speeds. These curves are more qualitatively similar to the performance of the balanced motor than those for the previous tests. Other test data for stable operating conditions are summarized in Table I, where the figure references give the test condition or calculation.

Considering that the rated current for the motor is 18.2 amperes, it can be seen from the data, Table I, that there exist several rotor connections at several speeds where the motor might be operated without exceeding this rating very much. For example, using the single-phase rotor connection with zero external resistance,

Figure 8. Torque-speed characteristics obtained from tests with external resistance in one rotor phase. (R is referred to stator)

a torque of 28 pound-feet can be developed with a current of 19.9 amperes at 47.6 per cent of synchronous speed. The rated full-load torque of the balanced machine is calculated to be 31 pound-feet, so that almost rated torque can be carried at the reduced speed without unreasonable stator current. This is done at an efficiency of 74 per cent, a much higher value than could be realized with the balanced machine.[1] Similar results can be observed in the data for some of the other rotor connections.

The data also show that the motor having greatly unbalanced connections has quite a low power factor; for the example above being only 41 per cent. Another disadvantage of the single-phase rotor is the vibration caused by pulsating torque, which has not been discussed here. These vibrations, in general undesirable or possibly damaging, would have to be considered in the design of the machine if it were built for such operation.

Conclusions

1. The performance of the induction motor with unbalanced rotor impedances is analyzed by the method of symmetrical components. Sequence components of the currents, the voltages, and the fields in the machine are treated separately, and the results superposed.

2. An unbalance in the rotor circuit causes unbalanced currents of slip frequency in the rotor phases, and balanced components of current in the stator at two frequencies, one of fundamental frequency and the other a subharmonic, the frequency of which depends on the speed.

3. The motor with single-phase rotor is similar in operation to two identical motors connected in concatenation.

4. The unbalanced rotor results in a torque-speed characteristic with two positive

Figure 9. Torque-speed characteristics obtained from tests with external resistance in two rotor phases. (R is referred to stator)

peaks, the larger occurring at slightly less than half synchronous speed, and with a dip occurring at slightly greater than half-speed which may extend into the negative torque region, depending on the degree of unbalance. The motor may operate stably at two speeds.

5. An equivalent circuit for a motor with unbalanced rotor can be derived if two of the external rotor impedances have the same value. It consists of a positive sequence network, a negative sequence network, and a connecting network which depends on the external impedances. This equivalent circuit simplifies computation of the various components of motor currents.

6. The induction motor with unbalanced rotor circuit may develop rated torque at reduced speed without excessive stator current, and with a higher efficiency than the balanced machine at the same speed.

7. The principal disadvantages of the motor operating with unbalanced rotor are the low power factor, the decreased maximum torque, the subharmonic frequency current impressed into the power supply lines, and the vibrations present when the rotor circuit is greatly unbalanced.

8. There may be instances where it is desirable to operate an induction motor at half speed as a temporary measure, or intermittently, and the results of this investigation help in predicting the motor performance.

Discussion

M. A. Thomas (New Mexico State College, State College, N. Mex.): The unbalanced rotor problem seems to have experienced a considerable revival of interest. To my knowledge three schools have persuaded students to make a special study of the phenomenon within the past two years. This topic is seldom explained in college textbooks or in engineering handbooks. The present paper is of general interest since it summarizes the previous knowledge of the problem and brings to a satisfactory state the application of present-day theory to the problem.

The analysis, by means of symmetrical components, is adequate to explain the performance of the machine, and the equivalent circuits which have been developed permit the prediction of the characteristics in many cases. It should perhaps be pointed out that the two component currents in the stator, indicated by I_1 and I_4 in the equivalent circuits, are of different frequencies in the actual motor, hence the summation of these currents can only be indicated. I am sorry that the authors did not include some typical oscillograms of the stator currents to show how these two different frequencies combine at various speeds. Such records are of considerable interest and often surprising to those who are not acquainted with such phenomena.

I believe the authors are in disagreement with the definition of ASA standards in designating the current I_4 induced back into the stator of the machine a subharmonic current. The frequency of this current will vary with speed and only at a few particular speeds will it bear an harmonic relation to the line frequency. The usual situation will result in the two currents swinging in-phase and out-of-phase at a rate depending upon the difference of the two frequencies. This produces fluctuations in the magnitude of the resultant current which are quite noticeable on an ordinary ammeter. At standstill the two component currents are of the same frequency. They will then result in unbalanced effective values in the three lines. The particular condition of unbalance will depend upon the relative position of rotor and stator.

The power system lines and load may receive an appreciable effect from the odd frequency currents which flow in the stator as the result of this phenomenon. Several years ago the community in which I live was troubled intermittently by flickering of incandescent lamps over a residential and rural area of several square miles. This difficulty was similar to, but more pronounced than, that caused by operation of lamps on 25-cycle power. The cause of the

trouble was finally traced to a 100-horsepower wound-rotor motor which was driving a cotton gin. After careful inspection of all parts of the motor a poor connection was finally discovered in the rotor controller. It can be assumed that the flickering of the lights was caused by the occasional single-phase operation of the rotor of this motor. Had the power company engineers been familiar with the phenomenon described in this paper they would have been able to analyze the trouble and to locate the defective circuit much more quickly.

Stephen Freeman, Jr. (Purdue University, Lafayette Ind.): It may be worthwhile calling attention to the very real effects which the Goerges Phenomenon may have where low capacity power supplies feed motors whose capacity approaches the same order of magnitude as the transformer, lines, and other nearby parts of the power supply network. Faulty operation of these motors caused by accidental impedance unbalances can be readily detected in noticeable voltage flicker in the power supply system, affecting all customers in the general vicinity of the motor. Recognition of the existence of the Goerges Phenomenon has led, in several cases in my experience as engineer with a power company, to solution of the flicker problem in the power lines as well as helped to speed correction of faulty motor operation.

G. W. Heumann (General Electric Company, Schenectady, N. Y.): The Goerges Effect as such is a very interesting phenomenon, but it has not found practical application for the speed control of induction motors. The analysis presented by the authors leads, however, to a more thorough understanding of the phenomena which may occur when a wound-rotor induction motor is started or speed-controlled with unbalanced resistance in the rotor circuit.

Many drum controllers for the secondary control of wound rotor motors use a circuit on the first step which is the equivalent of the one shown in Figure 7 of the paper. The advantage of this circuit is that a smaller secondary resistor is required to obtain a certain reduction in starting torque, than would be required with a symmetrical 3-phase resistor. Referring to Figure 1(A) of this discussion, a resistance R in each rotor phase would produce a starting torque of one half of that obtained with all three rotor phases connected to the Y point. Expressed differently, with all three phases connected to the Y point, a resistance of $2R$ would be required to obtain the same starting torque. On the second step of a drum controller, the third rotor phase is connected to the Y point, thereby doubling the starting torque and permitting the motor to accelerate on a symmetrical and balanced rotor circuit. Since the single-phased starting connection results, as the authors have pointed out, in possible severe vibration of the motor at half speed, the unbalanced starting connection should not be used for large motors, and its application is generally restricted to motors of 75 horsepower or less.

Figure 1. Wound rotor motor with unbalanced secondary resistor

Referring to Figure 7 of the paper, the rated torque of the 5-horsepower test motor (with a synchronous speed of 900 rpm) is approximately 30 pound-feet. Thus, the curves marked $R=9.44$ and $R=22.8$ (which would correspond to $R=4.72$ and $R=11.4$ in Figure 1 of this discussion) would produce starting torques of approximately 0.7 and 0.35 per unit respectively. This is the order of magnitude for which starting resistors are designed for material handling equipments, movable bridges, and similar applications. Examination of Figure 7 of the paper indicates that the dip in torque at one half synchronous speed is not very pronounced and will permit a lightly loaded motor to accelerate past that speed.

When the drum controller is advanced toward the full-speed position, resistance may be cut out in unequal steps, making every other controller point balanced and in-between points unbalanced. Figure 1(B) of this discussion shows the rotor circuit in a generalized manner. The degree of unbalance is generally moderate, hardly exceeding a 1 to 2 ratio between resistor phases. Speed-torque curves would be similar to those shown in Figure 9 of the paper, with the torque dip at one half speed of minor proportions. On the next-to-the-last point of the drum controller, a connection similar to the one shown in Figure 8 of the paper is used, where resistance in two rotor phases is short circuited and resistance left in the third phase. In order to avoid rough acceleration on the final controller point, resistance R will hardly be higher than 0.2 per unit of normal (where normal ohms is that resistance in each balanced rotor phase which would obtain unity starting torque) or, in terms of the authors' test motor, R will not exceed approximately 1.8. Examination of Figure 8 indicates again a moderate torque dip at one half speed.

Referring to Figure 1(B) of this discussion, the control designer is interested in knowing what motor performance he may expect from his motor for certain values of secondary resistance. Experience has shown that the following approximations obtain reasonably good results. If the variation in speed due to load changes is to be determined (which will occur at speeds above one half), an effective resistance

$$R_{eff}=\frac{R_1+R_2+R_3}{3}$$

may be used. If it is desired to determine the starting torque, calculation with an effective resistance

$$R_{eff}=\frac{R_1R_2+R_2R_3+R_3R_1}{R_1+R_2+R_3}$$

obtains better results.

In conclusion it may be stated that the findings of the authors are in agreement with practical experience gained over many years with unbalanced drum controllers. The Goerges effect need not be feared in connection with the design of resistors used with such drum controllers, provided the degree of unbalance between phases is moderate.

Harold L. Garbarino and **Eric T. B. Gross:** M. A. Thomas is quite correct in pointing out that a subharmonic is defined[1] as an integral submultiple of the fundamental. The subfrequency currents in the stator vary with the rotor speed and cover a whole frequency band; we are very grateful for this correction, however, we hope that the explanation in the text brought out the real character of the subfrequency currents.

It is very interesting that both Mr. Freeman and Mr. Thomas had the opportunity to observe some of the practical consequences of the Goerges phenomenon. Perhaps our textbooks should mention the effects of unbalanced rotor impedances, and some time may be devoted to such motor operation in college courses on a-c machinery. We know that Professor Harry Baum at the School of Technology of City College of New York included the Goerges phenomenon in his course for many years, and at Illinois Institute of Technology one full laboratory period has been devoted to it since 1946. The students' gain is a better understanding of induction machine operation in general.

Some other important practical applications are pointed out by Mr. Heumann, whose discussion is a valuable supplement to our investigation. We wish to thank the discussors for the interest they have shown in this paper, and for their comments.

Critical Inside Dimensions for Power Cable Manholes

EDWARD S. HALFMANN
ASSOCIATE AIEE

THE THREE basic approaches to manhole design are: duplication of existing design; modification of existing design to eliminate certain known defects or inadequacies; and new design based on recently developed methods of predicting cable sheath life. This paper deals primarily with the latter, but it is well to keep in mind that existing design has been given a field test, whether formal or informal, and that the lessons learned from experience are extremely valuable. Since manholes and allied underground structures are of so many different sizes and shapes depending on the purpose which they serve, it has been necessary to limit the scope of this paper to power cable manholes and in particular, to the manholes along the route of transmission or express circuit cable lines.

The useful life of a modern paper-insulated lead-covered cable is essentially equal to the life of its sheath. Cable failures today can rarely be attributed to natural aging of the insulation. Almost every cable failure can be traced to a break of some kind in the lead sheath which has allowed moisture to enter the cable and cause insulation deterioration. Adjacent to the bends of a cable in a manhole, circumferential cracks caused by mechanical fatigue of the lead develop in the sheath. These cracks are produced by the repeated flexing of the cable which is necessary to accommodate the longitudinal movement of the cable at the duct mouths. The cable movement in turn is produced by changes in load on the cable causing it to expand and contract longitudinally in the duct between manholes. The rate of development of the cracks is dependent on the movement of the cable at the duct mouth and on the dimensions of the cable offset in the manhole. Cable movement cannot readily be controlled but the length and the width of the offset can be so chosen to produce the desired cable life.

Halperin[1,2] pioneered in the study of cable movement and its relationship to sheath life. Schifreen[3,4,5] obtained actual charts of cable movement at the duct mouth as a function of time and load current. Through a stress-strain analysis of the sheath at bends in the manhole, Schifreen developed a method of calculating the life of a cable for a given length and width of offset in the manhole. By making certain assumptions, Schifreen's method can be reduced to the single composite graph shown in Figure 1. By using this chart, the relationships between load, life, and offset dimensions for a given cable can readily be obtained.

Use of the Chart

The chart in Figure 1 may be used: to find offset dimensions which will produce the desired life of a cable under given load conditions; to find the life of a cable under given conditions of load and offset dimensions; or to find the load which will produce the desired cable life in a given manhole. It is necessary to know or to assume the conductor size and voltage rating of a cable before the chart can be used. The voltage rating of the cable is set by the system in which the cable will operate and the conductor size is usually determined by the normal and emergency current carrying requirements.[6] Tables I, II, and III have been prepared so that the factor (K) for frequently used cables would be readily available. K is equal to the a-c resistance of one conductor in ohms per foot multiplied by the thermal resistance from one conductor to the duct in degrees centigrade per watt for one foot of cable.

To find the length and width of offset which will produce the desired life for a given cable, proceed as follows:

1. Determine the minimum 4-hour average current and the maximum 4-hour average current for a representative working day. Divide the former by the latter and express the quotient in per cent.
2. Enter Section I of Figure 1 at the maximum 4-hour average current.
3. From the intersection of the maximum 4-hour average current and the per cent minimum-maximum determined in step 1 trace horizontally across the chart to the proper value of K in Section II, from which the daily conductor temperature range may be found if desired.
4. Trace vertically upward to the proper cable outside radius in Section III, from which the daily cable movement at each duct mouth may be obtained if desired.
5. From the intersection in Section III, trace horizontally to the desired cable sheath life line in Section IV and then vertically downward into Section V.
6. In Section V, a number of combinations of offset length (L) and offset width (F) along the vertical trace and above the minimum allowable bending radius (R) will satisfy the sheath life requirement. Select the combination most suitable for the particular location concerned. The minimum allowable bending radius for a cable may be taken as 12 times its outside diameter.

To find the expected life for a given cable in a given manhole, the procedure is the same as for finding offset dimensions as far as entering Section IV of the chart with a horizontal trace. Then a vertical trace is drawn from the intersection of the known width and length of offset in Section V. The intersection of this vertical

Paper 50-256, recommended by the AIEE Insulated Conductors Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, October 23–27, 1950. Manuscript submitted May 31, 1950; made available for printing August 25, 1950.

EDWARD S. HALFMANN is with the Philadelphia Electric Company, Philadelphia, Pa.

Figure 1. Manhole design chart

trace with the horizontal trace indicates the expected sheath life.

To find the loading of a cable which will produce the desired sheath life in a given manhole, start at the intersection of known width and length of offset in Section V and trace back through Sections IV, III, II, and I. In Section I, it will be found that a number of combinations of maximum 4-hour average current and per cent minimum-maximum along the horizontal trace will produce the desired sheath life.

Manhole Dimensions

In general, the only dimensions affecting the life of a cable in a manhole are the length and width of offset which can be determined from Figure 1. The remaining dimensions must be determined by the space required for working in the manhole and for equipment to be installed. The number and arrangement of ducts entering the manhole are important. The ideal arrangement for a straight manhole is two ducts wide at each end of the manhole as shown in Figure 2. This permits racking the cables in single tiers along each side wall which provides excellent accessibility to the joints. It also eliminates the necessity of moving one cable to work on another. The "2-wide" arrangement may be further improved by staggering the vertical position of the ducts as shown in Figure 2. This permits a cable entering at one side to be

Values of K were determined from Table 20, page 35 of reference 6.

racked on the opposite side wall without interfering with any other cable. A 2-wide duct arrangement permits a minimum width of manhole and offers a duct bank with excellent heat dissipating properties. Every duct can be fully utilized but the cost of such a duct bank is usually higher than other configurations. If this added cost of duct bank is not justified by thermal requirements, it is possible to change duct configuration adjacent to the manhole that is, change from a 2 by 6 bank at the manhole to a 4 by 3 bank in the major portion of the duct run.

When the number of ducts is large, a 2-duct-wide manhole may need too high a ceiling to be practical. It has been found advisable to locate the lowest joint in a manhole at least 18 inches above the floor so that a splicer may make a good joint even if the floor is wet. Likewise the top joint should be at least 2 feet below the ceiling to afford good working conditions. For a 2 by 6 duct manhole this requires about an 8-foot ceiling. The disadvantage of a high ceiling is offset to some extent by the fact that the manhole can be made narrower than it would otherwise be with other racking arrangements.

The minimum inside length of a straight manhole is the length of a joint plus the lengths of the two cable offsets. The manhole width is determined by the space between ducts, the width of the offset and the allowance for the cable joints to move toward and away from the side walls. The sideways motion due to daily load cycle is small but over a period of time, movement is considerable at some locations due to the tendency of the cable to gradually creep into one manhole from another. In general a distance of 8 to 12 inches from the wall to the axis of the cable and joint is ample.

There are two general shapes of straight manholes; rectangular and the so-called "coffin shape." The "coffin shape" manhole requires a little smaller excavation, provides a stronger design, but requires more costly forms if it is to be of concrete.

Figure 2. Precast straight transmission manhole

The design of corner manholes is not so critical with regard to cable sheath life as straight manholes since the corner bend itself tends to relieve the stresses in the cable due to expansion and contraction. The important factor in corner manhole design is to see that the cable is not bent sharper than the minimum bending radius of the cable. This is conservatively given as 12 times the outside diameter. It is, however, advisable to provide a cable offset at one end of the manhole as shown in Figure 3. It also is important to provide for ample sideways movement of the cable on the racks in this type of manhole.

Precast manholes have recently come into use in a number of cities. A precast manhole may be cast in carefully assembled steel forms at a fabricating plant and accurate manhole dimensions can be obtained. The forms may be reused and the number of duct openings altered. A precast manhole can be installed in the field much faster than a cast-in-place manhole and may be used as a caisson during excavation which saves the cost of shoring, Figure 4. Manhole sections up to 14 tons in weight can be brought to the location on trailer trucks and lifted in place by a 20-ton truck crane. Lifting eyes must be provided to facilitate handling with a crane. The wall section is reinforced so that it will be self-supporting when lifted and that it will withstand the maximum pressure which may be exerted from the outside. When this wall section is in position, a sufficient number of building blocks are placed under the walls to support it and then a concrete floor is poured in place. A water sealing compound is placed at the joint between the walls and the floor. A sump is cast into the floor so that water on the floor will drain into the sump and may readily be pumped out.

The roof slab, Figure 5, is precast and lifted in place by the crane. It is designed to be not only self-supporting but also to be able to support a wheel load of 25,000 pounds. A step around the edge of the casting, Figure 2, locks the roof in place on the walls and a water seal is installed to prevent leaking. In order to permit the same manhole to be used at different depths, an adjustable opening is provided. If the roof is close to the surface,

precast concrete slabs are installed to reduce the size of the opening and the manhole frame is supported by bricks. If the manhole is deeper, an access shaft of the proper length is cast after the roof is in place. With this added feature of flexibility, it is possible to use precast manholes at many more locations than would otherwise be possible.

Appendix. Derivation of the Chart

Sections I and II of Figure 1 establish the relationship between the loading of the cable and the daily conductor temperature range. For purposes of this analysis it has been assumed that the duct bank temperature remains constant during any one load cycle and that the cable will reach its ultimate temperature change in four hours following a change in load. It has been found that by using the average of the maximum four consecutive hourly ammeter readings and the average of the minimum four consecutive hourly ammeter readings, the daily conductor temperature range can be obtained with reasonable accuracy.

For a constant load on a cable, the temperature of the conductor above the temperature of the duct bank can be expressed as follows:

$$T_c - T_d = I^2 r_{cond} R_{th} \qquad (1)$$

where

T_c = conductor temperature in degrees centigrade
T_d = duct bank temperature in degrees centigrade
I = phase current in amperes
r_{cond} = a-c resistance of one conductor in ohms per foot
R_{th} = thermal resistance from one conductor to duct in degrees centigrade per watt for one foot of cable

Equation 1 may be written for the maximum 4-hour current and the minimum 4-hour current and the difference will then be the daily conductor temperature range.

$$T_{c_{max}} - T_d = I_{max}^2 r_{cond} R_{th} \qquad (2)$$

$$T_{c_{min}} - T_d = I_{min}^2 r_{cond} R_{th} \qquad (3)$$

$$T_{c_{max}} - T_{c_{min}} = (I_{max}^2 - I_{min}^2) r_{cond} R_{th}$$

$$\Delta T_c = (I_{max}^2 - I_{min}^2) K$$

$$\Delta T_c = I_{max}^2 \left[1 - \left(\frac{I_{min}}{I_{max}} \right)^2 \right] K \qquad (4)$$

K represents the product of r_{cond} and R_{th} and is given in Tables I, II, and III for frequently used cables. ΔT_c is the daily range of conductor temperature in degrees centigrade. The product of I_{max}^2 and the expression in the bracket is obtained graphically in Section I of Figure 1 and this is multiplied by K in Section II of Figure 1 to obtain daily range of conductor temperature.

The relationship between daily range of conductor temperature and cable movement at a duct mouth is based on the test data curve in Figure 15 of reference 5. This indicates that cable movement at a duct mouth for cable runs of 300 feet or more may be expressed as follows:

$$M = (\Delta T_c - 5) 0.03 \text{ inch} \qquad (5)$$

More recent studies taking into account duct irregularities indicate that 80 per cent of this value is more nearly correct for relatively long duct runs, hence the relationship used in Figure 1 in obtaining the movement scale of Section III is:

$$M = (\Delta T_c - 5) 0.024 \text{ inch} \qquad (6)$$

The relationship between cable movement, strain in the sheath and offset dimensions is based on the per cent strain equation developed in Appendix A of reference 3.

$$\epsilon = \frac{850 r \sqrt{F^2 + LM} - F\sqrt{F^2 + 2LM - M^2}}{L^2 + F^2} \qquad (7)$$

Figure 4. Precast manhole partially installed

where

ϵ = per cent strain in the sheath
r = outside radius of the sheath in inches
F = width of offset in inches
L = length of offset in inches
M = cable movement in inches

This equation may be expressed as

$$\epsilon = 850 r f(F, L, M) \qquad (8)$$

When $f(F, L, M)$ is evaluated for a number of values of F, L, and M, it is found that, for the range of values applicable to manhole design, this function is directly proportional to M. The expression may, therefore, be rewritten

$$\epsilon = 850 r M f(F, L) \qquad (9)$$

The relationship between sheath life in load cycles and maximum per cent strain of the lead is obtained from Figure 11 of reference 5. This curve may be converted to years life by assuming 275 load cycles per year

PLAN

Figure 3 (left). Cast-in-place corner transmission manhole

Figure 5 (right, below). Precast manhole roof

and may then be expressed by the equation

$$S = 1.6e^{-1.44} \tag{10}$$

where S is sheath life in years and e is maximum per cent strain in the sheath. This can be rewritten:

$$e = 1.39S^{-0.7} \tag{11}$$

Combining equations 9 and 11 we have

$$1.39S^{-0.7} = 850rMf(F, L) \tag{12}$$

or

$$\frac{1.39S^{-0.7}}{Mr} = 850f(F, L) \tag{13}$$

The product of $M \times r$ is obtained in Section III of Figure 1. The term $1.39\ S^{-0.7}$ is divided by $M \times r$ in Section IV of Figure 1 and equated to $850\ f(F, L)$ which is evaluated in Section V.

The bending radius lines superimposed in Section V are obtained from the equation

$$R = \frac{L^2 + F^2}{4F} \tag{14}$$

The bending radius lines merely serve as a guide in selecting offset dimensions and do not enter directly into the solution of the problem.

Discussion

H. A. Adler and **K. H. Wadleigh** (Commonwealth Edison Company, Chicago, Ill.): This paper is a convenient and condensed presentation of the method of calculating sheath life as proposed by C. S. Schifreen (see references 3, 4, and 5 of the paper). Instead of having to refer to several graphs and formulas, Figure 1 of the paper makes it possible to solve the problem in one continuous process.

This graph is satisfactory if Schifreen's method is accepted as the basis of sheath life calculations. However, some of its limitations should have been made clear in order to avoid misleading conclusions. Figure 1 applies only to copper bearing lead sheath and not to alloy sheath. It applies to a sheath temperature of 40 degrees centigrade. The amount of cable movement is based on data for 1,500,000 circular mil, 66-kv oil-filled cable with a diameter of 2.44 inches. Other cables may be much more flexible and may have less movement. Furthermore, differences in friction and variations in duct profile may produce different movements. The movement given in Figure 1 is the average movement per duct mouth. Schifreen has presented statistical diagrams which indicate that due to unequal movement on the ends of a length, the movement may be considerably more than average at one duct mouth. Similar data were presented in Figure 10 of a paper by Herman Halperin.[1]

Figure 1 applies specifically to standard straight-type manholes with free moving joints. There are several simplifying assumptions to facilitate the graph, but they appear acceptable within the accuracy of this method. With these qualifications, we consider this method a very convenient procedure for determining sheath life.

Reference

1. See reference 2 of the paper.

W. A. Del Mar (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): The author assumes that cables in ducts will attain their maximum temperature in four hours. Is this assumption based on observations under operating conditions?

I take exception to the author's assumption that his values of K, derived from Insulated Power Cable Engineers Association's tables of carrying capacity in free air, are applicable to cables in ducts. This assumption is so far from being correct that it throws considerable doubt on the accuracy of his method.

C. T. Hatcher (Consolidated Edison Company of New York, Inc., New York, N. Y.): Mr. Halfmann has presented in a practical and useful form the results of a very detailed investigation of cable manhole sizes as related to cable life.

The maintenance of the integrity of the cable sheath has been a continuing problem in utility companies having underground systems and the situation has been aggravated in many companies by the tendency toward greater feeder loading, producing increased cable movement, and by the installation of larger cables in old duct and manhole systems.

When building new duct systems, particularly those intended for important tie feeders, the installation of manholes sufficiently large to permit adequate offsets for optimum cable life may be justifiable on an economic basis. The straightforward solution of installing wide manholes so as to permit horizontal offsets may not be possible of attainment in many cases since the manhole would become an intolerable obstruction of lanes assigned to other subsurface utilities such as gas, steam and water mains, sewers, and telephone ducts.

An alternative would be the building of manholes of normal width, but of greater than usual depth to permit offsets to be made in a vertical or sloping plane. This alternative solution may sometimes introduce other objectionable features such as bringing the floor elevation down into tide water levels or placing floor levels below the sewer system elevation. If the ducts are brought in low and the joints are racked high in the manhole, additional excavation is required to lower the duct bank near the manholes and these pitches in the duct bank produce a less desirable situation from a cable-pulling standpoint. Means for supporting the cables in the manholes at intermediate points between the joints and the duct mouths are also complicated.

A variation of the symmetrical cable racking normally employed in rectangular manholes would be to have the duct entrance location at one end of the manhole near one side wall and at the other end, near the opposite side wall. Each cable passing through the manhole would have a full wide offset at one end of the manhole and almost none at the other end.

Experience with 138-kv oil-filled cables in manholes of this type has been good and that design was recently employed in a 69-kv oil-filled cable installation. It would be of interest to compare the expected life of cables racked in this way in a given manhole to the life anticipated in the same size manhole if the duct entrances were centered and two complete, although small, offsets are employed. It would also be of interest to determine the advantages of having wide offsets at both ends of the manhole as compared with having a wide offset at one end only.

The "unsymmetrical" scheme just described, embodying an offset at only one end of each manhole on any particular cable, would make it seem desirable to install left and right manholes so that the duct entrances of adjacent manholes would be properly positioned with respect to each other.

If this were not done, it would be necessary to deflect the duct bank as it approached the manhole to meet the off-center point of entrance.

The author's suggestion for staggering duct mouths and crossing cables within the manholes does provide a means for gaining greater cable offsets without increasing the width of the manholes materially, although access to the duct mouth for cable pulling and for installation of fairleaders, duct sealing, installation of bond ties, and arcproofing are made less easy.

With regard to the use of precast manholes, the practice in New York is similar to that described by the author, with the exception that floors are also precast in New York. One of the greatest advantages in the use of these manholes in metropolitan areas is the fact that the street opening may be closed much more rapidly and normal unimpeded traffic flow resumed.

Robert J. Wiseman (The Okonite Company, Passaic, N. J.): This paper is very helpful in appreciating the factors that influence the design of manholes. This part of a cable system, like ducts, has become a

highly technical and engineering problem. If it had been appreciated years ago that the life of a cable depends on how it is installed in a manhole, many cables would have had a longer life. Reading this paper explains why manholes must be increased in dimensions to take care of present day cables.

The author has presented a very fine method for determining the dimensions of a manhole for a given cable or what the life of a cable may be knowing the manhole dimensions. This will be very helpful to a design engineer. I would like to ask the author if there is an optimum value of "R" the width of offset of the center of the cable in the duct from the center of the joint and "L" the length of offset from the edge of the duct wall to the end of the joint. Figure 1 of the paper shows how both vary but is there some particular value that would be preferred, say as a function of the diameter of the cable. The author suggests as a value of "R" the radius of bending of the cable as 12 times the over-all diameter. It seems to me as if this is too high as it would mean large manholes. We have used a value of ten times the outside diameter and even as low as eight times on small cables.

The chart as set up in Figure 1 is based on using copper bearing lead. Could the author estimate what changes he would make if an alloyed lead such as the arsenical types were used? As a first guess could we say the life would be doubled?

Can the author give an idea of the relative cost of manholes today as compared to pre-World-War II?

E. S. Halfmann: The comments and questions of the discussors are greatly appreciated by the author and indicate a genuine interest in a simplified approach to manhole design.

As pointed out by H. A. Adler and K. H. Wadleigh, the chart in Figure 1 may be used for cable having commercially pure or copper bearing lead sheath and is not applicable to cables with alloy sheaths. The relationship between daily cable movement and daily copper temperature range was obtained by taking the test curve for 1,500,000 circular mil, 69-kv oil-filled cable shown in Figure 15 of reference 5 of the paper and modifying it in accordance with field experience on all sizes of cable. Equation 6 in the Appendix which was used in setting up the chart is therefore representative for movement of all large single- and 3-conductor cables and is in keeping with the field observations reported by Mr. Halperin in reference 2 of the paper. The daily cable movement as indicated in Figure 1 is, of course, the average movement which may be expected. The actual movement at a specific location may vary from 0 to 200 per cent of this value as illustrated in Figure 14 of reference 5.

Mr. Del Mar has questioned the propriety of using a 4-hour time constant for cable in underground duct. A duct bank in which cables have the same load cycles day after day remains at nearly constant temperature. Tests have indicated that the variation in temperature under these conditions may be a degree or less during any 24-hour period. It is therefore reasonable to assume that the duct bank temperature is constant. The long thermal time constant of a duct bank observed when a cold duct bank is first loaded has no bearing on the daily cable movement problem.

Tests on 3 × 250,000 circular mil and 3 × 500,000 circular mil 5-kv cable in duct indicated that the cables attained 80 to 86 per cent of their ultimate temperature rise above duct in four hours. This value will vary somewhat with different types of conduit and with cable size. Most cables, however, have an attainment above 80 per cent in four hours. A complete determination of daily temperature range could only be made by the use of a specifically designed temperature rise indicator[1] or by an hour-by-hour transient calculation of temperature variation with load. A short cut to this laborious calculation is to use the average of the four maximum hourly ammeter readings and the average of the four minimum hourly ammeter readings, and assume 100 per cent attainment. It has been found that for most load cycles and cable types, this method will give a remarkably close approximation.

The values of K in Tables I, II, and III are based on the Insulated Power Cable Engineers Association values of thermal surface resistivity as defined in reference 6. Studies by J. H. Neher,[2] have shown that cable-to-duct thermal resistance for cable in concrete inclosed fiber duct is very nearly equal to the values obtained by this method. The thermal resistance in concrete duct or concrete-inclosed transite or terra cotta duct is slightly lower. Accordingly the values of K vary slightly with different types of duct construction but these variations are small and may be neglected.

Mr. Hatcher has pointed out that in some manholes the cable is brought in straight at one end and the entire cable movement must be taken up by the offset at the opposite end. This method of racking would require provision to be made for the joint to move longitudinally as well as laterally. The mathematical analysis of the strains in the sheath would be different in this case than in the case of the symmetrical manhole and hence Figure 1 may not be used directly for this type of construction.

In reply to Dr. Wiseman, there does not appear to be any mathematical optimum ratio of length of offset to width of offset provided the bending radius of the cable is greater than its minimum allowable bending radius. This ratio should be determined by practical considerations in the manhole. Dr. Wiseman has pointed out that alloy lead sheaths will outlast copper bearing lead sheaths on fatigue tests. This is true, but adequate information on alloy lead sheathed cable is not available in order to predict sheath life by the method used in Figure 1.

In conclusion it should be pointed out that certain limitations must be observed. However, for nonalloy sheathed cable in symmetrical manholes, this method can be relied upon to determine the appropriate manhole dimensions and to predict cable sheath life.

Underground Conduit for Electric Power Systems—Fundamentals and Basic Design Considerations

E. G. WATKINS
NONMEMBER AIEE

THE intent of this presentation is to discuss the fundamentals and basic considerations involved in the design of conduit systems for transmission and distribution of electric power. The design of other distribution structures, such as manholes and boxes, is not included and only the influence of those structures on the design of conduits will be considered herein.

General Considerations

Fundamentally, a conduit system is good or bad depending upon its suitability for the installation, operation, protection, and maintenance of the cables which it is to contain. Fundamentals and basic considerations for conduit design and the construction of conduit systems are not essentially different now than they have been in the past but progress in the art frequently adds or detracts emphasis. For example, the growing tendency to install cables of greater capacity and to carry higher loads in existing systems adds emphasis to thermal requirements. Probably, the only new development in recent years involving conduit construction is the installation of high-voltage transmission cable in steel pipe with gas or oil under high pressure. This type of construction is much closer to oil and gas line construction than to conventional conduit construction and has been discussed in detail in recent articles in trade and engineering journals. The cost and lack of flexibility usually restricts this system to transmission uses.

It is presupposed that other electric transmission and distribution systems have been considered before undertaking the design and installation of an underground system. Installation of cables in an underground conduit system is usually the most expensive method of distributing electricity except in congested city areas where load densities make an overhead system impractical. Buried cable, without the use of conduit, is economically attractive in some instances. Aerial cable also may provide a less expensive system than conduit. The use of combination overhead and underground construction is frequently economical, particularly in suburban areas where there are civic or political objections to overhead services. One combination gas and electric company finds such a system to be practical.

In some suburban sections of their territory, the secondary electrical distribution ducts are installed in a common trench with the gas main while primary feeders and transformers are carried on poles and feed the secondary system by means of pole risers. Compared to an overhead system, the initial cost of a conduit system is high. There is some compensation, however, in the fact that the maintenance cost on a percentage basis is less than for an overhead system.

The complexity of the design problems pertaining to an underground conduit system will depend on whether it is intended as a new system in which there will be a greater flexibility of choice with respect to materials and methods or whether it is intended to extend or modify an existing underground conduit system, in which case the design must be made to accommodate certain features of the existing system. In any event, the basic principles of design, whether for a new system or for the extension and modification of an existing system, are the same. Co-ordination and compromise are usually necessary to attain the most satisfactory electrical, mechanical, and economical arrangement.

A standard underground conduit system can usually be adopted by a utility company which has or is planning to install its electrical transmission and distribution facilities underground. In order to standardize, conduit material and the design installation must be made to conform with general conditions. Special methods should be reserved for locations where, because of either cost or physical conditions, standard procedures would not be satisfactory. The ideal design for a particular set of circumstances can be more closely approached in the case of a conduit installation for industrial usage or as a through route for feeders between electric switching or generating stations.

Design Considerations

Fundamentals and basic considerations involved in the design of conduit systems include such known factors as:

1. General route.
2. Number and size of cables.
3. Purpose for which the system is to be used.
4. Thermal requirements.
5. Physical obstructions.
6. Character of soil.
7. Number of spare ducts for future extension.
8. Other limitations, such as municipal regulations.

The following items permit a wide variety of choice and the decision of selecting the most satisfactory choice to

Paper 50-257, recommended by the AIEE Insulated Conductors Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted June 6, 1950; made available for printing August 25, 1950.

E. G. WATKINS is with the Consolidated Edison Company of New York, Inc., New York, N. Y.

suit any particular situation becomes a problem of the design:

1. Layout in street.
2. Kind of conduit material.
3. Size of conduits.
4. Arrangement of conduits.
5. Construction details.

Layout in Street

The location of conduit systems in streets is influenced by such factors as existing street facilities, subsurface structures, width of street, type of pavement, sidewalk arrangements, type of conduit and manhole installation, number and character of services, manhole locations, cover, probability of damage from street excavations, municipal regulations, and possibly some others. Interference with other subsurface structures probably represents the most difficult problem. It usually requires considerable planning to keep a conduit line reasonably straight and avoid water mains and services, surface water drains, sewers, gas mains, telephone conduits and manholes, and sometimes underground steam mains. Both in the interest of straight conduits and future maintenance, a street lane at a standard distance from the building or curb line is usually desirable.

For an express run, the location in the street may not be important, but where services must be supplied, the width of the street will probably determine the economics of whether conduits should be installed on one or both sides of the street or in the middle. The middle of the street is usually reserved for sewer construction. Since manholes and service boxes generally require more lane space than conduits, it is usually desirable to locate those structures first and then readjust them later, if necessary, to achieve the best over-all location for the complete underground system. When more than one electrical feeder is to be installed along the same general route, it is considered desirable practice to install them on separate streets if economically feasible.

Principal disadvantage	Magnetic	Magnetic	Envelope expensive	Effect of water	Heavy	Difficulty of stacking	Brittle	Communication of electrical faults	Difficulty of stacking	Envelope expensive	Decay

This serves the purpose of preventing communicating faults by having feeders in the same manholes and also serves to limit the damage, should there be an extensive underground disturbance, for example, the breaking of a large water main.

Every bend in a conduit increases the force required to pull cable. Hence, the number, character, and radius of the bends affect the maximum length between splice points. The greater the angle of the bend, the greater the resistance to cable pulling. It is virtually impossible to install a conduit system without bends. The alternative to the reduction of the number of bends is to require more manholes—an expensive alternative. It is usually possible to lay out a system with not more than one major bend in a section between manholes, and this bend should be located near one of the manholes rather than in the center of the section. The cable-pulling tension at a bend is dependent upon the length of section between the feeding manhole and the bend. By keeping the bend close to the feeding manhole, cable-pulling tensions are lessened. Angle manholes have been used in some instances to avoid conduit bends. The effect of vertical bends to avoid obstructions also must be considered. Most frequently, these bends are of such slight angles and of such large radii that their effect is not appreciable.

A radius of curvature exceeding 300 feet adds so little to the pulling strain that such a curve can be neglected. Radii of curvature of less than eight times the duct diameter should not be permitted. In the design of a conduit system, bends of varying degree may be expressed as equivalent length of straight conduit; thus, for example, if it has been determined that the maximum length of straight pull should be 600 feet and a section contained a bend which was equivalent to 50 feet of straight conduit, the straight portion of this section should not

Figure 2. Conduit formations

All joints in the fiber, steel or transite conduits shall be staggered. Conduit separators shall be installed every eight feet for fiber conduit and every ten feet for steel and transite conduits. After conduits have been assembled with couplings and separators the assembly shall be fastened rigidly with two turns of number 18 iron wire every ten feet. When the side of the trench is compact, trench wall may be used as the form for the concrete envelope. Minimum cover on distributor conduits shall be 18 inches, on trunk conduits one foot 10 inches

Figure 5. Effect of bends expressed as equivalent length of straight conduit

exceed 550 feet. An example of a method of determining equivalent lengths is shown in Figure 5. Factors entering this problem are conduit material, permissible pulling stresses of the cable to be used, and the type and kind of cable to be installed.

The length of the sections of conduit may be determined by the need for manholes and boxes dictated by local service conditions. Where there is no need for splicing chambers because of local distribution considerations, the length of the conduit sections is determined by the pulling stresses required for the introduction of cable into the conduit system.

Conduit Materials

Any material appropriate for fabrication into a pipe or duct may be considered as a possibility for a conduit. The materials in general use today—not necessarily in order of use—are steel, laminated materials or homogeneous mixtures such as fiber and transite, ceramic materials such as vitreous tile, concrete–reinforced and unreinforced–round and square, wood and plastics. The most common are steel, fiber, concrete, transite, and tile.

The ideal conduit or duct material is one which is least expensive, is smooth to lessen cable-pulling stresses and minimize damage to cable being pulled, readily dissipates heat, has no objectionable magnetic effects, is free from properties deleterious to the cable covering, can be economically installed, will not deteriorate, and, if damaged, can be repaired readily. All of these factors must be balanced to obtain a most satisfactory compromise material.

The type of conduit material used will influence the design of the system. Such considerations as size, flexibility, resistance to corrosion, methods of construction, magnetic effects, heat dissipation characteristics, formation for racking and splicing in manholes, all enter into the selection of types of conduits and likewise affect the over-all design of the system.

Conduit Size and Shape

The size of the conduits required for the cables to be contained is a controversial subject because it involves the stresses cable engineers are willing to use in pulling cable and the thermal performance of various combinations. The answer to the question of the size of conduit to accommodate cable or vice versa, the number and kind of cable that can be installed in a conduit of a given size, depends upon the permissible pulling tensions. A frequently used "rule of thumb" is that the conduit diameter should be at least 1/2-inch greater than the diameter of a circle which would enclose the cables. A large diameter single lead sheathed cable ordinarily will require a duct having a diameter as much as 1 inch greater than the cable.

Conduits suitable for underground installation are generally available in almost any size desired. Single conduits are usually manufactured with a round bore. This shape is considered preferable for cable pulling since the cables are of round

Figure 6. Conduit entrances or terminations

Conduit seals shall be applied to the following

1. At the transformer manhole end of all conduits entering transformer manholes
2. At both ends of all conduits entering a transformer vault from a street or private property conduit system
3. At both ends of conduits between network vaults
4. At both ends of underground service conduits

Figure 7. Adaptor for service connection

cross section. A circular cross section is also the most efficient from a standpoint of strength and economy of material. The external cross section or shape of the conduit is of minor significance in single or double conduit construction. Square external cross-section conduits are advantageous when laid in bank formation of three or more. The outside square cross section readily permits the stacking of the conduits either in vertical or horizontal formation and avoids the necessity of using special shape separators. Banks of conduits made up of square outside cross section are quite stable and usually do not require concrete encasement.

The length of individual conduit pieces is usually determined by the particular manufacturing process and costs. Installation methods and handling also are factors in determining the length of conduit pieces. Heavy conduits, such as precast concrete, are limited in length in order that their weight may not be in excess of that which a man can ordinarily handle. Longer individual conduit lengths require fewer joints to be assembled in the trench and hence the installation cost is likely to be less expensive.

Table I shows types of conduit materials in general use and indicates some of their characteristics. Caution must be exercised in making use of the table for other than an index. Materials, methods of manufacture, prices, and even characteristics of materials are subject to change or modifications. Also because equal weight cannot be given to each item in the table and because local conditions may add or detract from the importance of the items, it is submitted only as an index and guide. For items where absolute values cannot be given, materials are compared relatively.

Configurations

The arrangement of conduits in a bank and the transition from one arrangement to another to meet field conditions is particularly important where duct banks are to be installed in streets where there are other facilities and where, as in large cities, certain utilities are assigned certain lanes in the street, see Figure 1. Street intersections in such streets offer particular problems. Needless to say, the configuration must usually be a compromise between what the cable engineer desires for best heat dissipation and conditions as existing in the streets. The principal difficulty arises when the arrangement must be changed to accommodate street interferences, manhole entrances, and the like. Where practical, it is desirable to have the duct bank conform to the arrangement of the duct entrances to the manhole to avoid the necessity for changing the conduit arrangement and to provide for convenient racking of cable within the manhole. Figures 2 and 3 illustrate some common conduit configurations. Figure 3 is a modification of a similar figure which appeared in the Underground Reference Book.[1]

Construction Methods

The method of installation of conduits depends upon more than the least expensive method of installing a given number of conduits in a trench of least expensive dimensions. The arrangement of conduits must meet the demands of cable engineers for satisfactory heat dissipation and minimum clearances must be maintained between conduits and other substructures. Heat dissipation requirements will influence both the arrangement of the conduits and the required cover. Sufficient clearance must be provided to provide working space around

Figure 8 (left). Service conduit for lamp posts

Figure 9 (right). Conduit construction at bridge abutment

Figure 10. Expansion joints at bridges

the conduits and adjoining substructures. A clearance of 12 inches is frequently specified. Within the limitations of heat dissipation and clearance requirements, the most satisfactory trench size must then be determined. Where pavement is a factor, it is frequently advantageous to arrange the conduits so as to make a trench deeper to save width. Where mechanical excavation is practical, the size and dimensions of the trench may be influenced by the trench dimensions most economically excavated by the digging equipment available. The amount and character of work to be actually performed in the trench must be considered.

The minimum cover required on a conduit or duct bank is dependent upon thermal requirements, the type of conduit materials, and the street loads to which the system might be subjected. Since live street loads become less important a factor as the depth of cover increases and earth loadings alone are not serious for pipes the size of conduit, excavation depth usually involves no problems except possibly sheeting the trench, see Figure 4. A cover of 18 inches is safe for most conduit construction and most street loads, and usually satisfies thermal requirements. Where less than 18 inches is obtained and surface loads are a factor, some provision should be made for protecting the conduit system from the street loading. Shallow cover also exposes conduit systems to damage when the street is excavated for installing other subsurface structures. Protection is frequently obtained by the use of steel plates or creosoted wooden planks. Either affords protection against damage from foreign street excavations; steel plate is more suitable for protection against street loading.

The bottom of trenches should be graded uniformly for proper alignment of the conduit. Where grading is difficult, for example in rock areas, a graded soil bed should be provided. It is usually advantageous to slope the conduits to drain to a manhole. Backfill placed around the conduits should be uniformly and firmly tamped to prevent future settlement. Compacting of the backfill by flushing with water should not be used because of the possibility of infiltration of fine soil into conduits. Precast concrete conduits and other conduits not in a concrete envelope usually are not sealed at the joints.

Bends of large radius, 100 feet or greater, can frequently be made by deflecting the joints. Smaller bends should be made with the use of manufactured conduit bends.

During the progress of installation, the ends of the conduits should be plugged if the job is halted for any period of time, such as overnight. After the installation is complete, the individual conduits must be cleared and their identity in adjoining manholes must be established especially where transposition has taken place. This is usually accomplished by "rodding"—insertion of short flexible jointed rods pushed from one manhole to the other. A mandrel, usually about 1/4-inch smaller in diameter than the conduits, preceded by a wire brush, is then pulled from manhole to manhole. Finally, if the conduits are to be occupied in the near future, a galvanized pulling wire of number 10 or 12 gauge, pulled in with the mandrel and brush, is left in the conduit for the convenience of cable-pulling crews.

There is equipment in use today for mechanically installing single conduits in a trench but usually conduits are installed in the trench by hand. Steel pipe and materials having fixed couplings can frequently be joined in long lengths before dropping or pulling into a trench in order to avoid the more inconvenient and usually more expensive coupling in the trench. Conduit materials such as precast concrete and tile must be assembled in the trench. In unpaved areas, single conduits have been successfully ploughed

Figure 11. Installation of conduits in unstable soils

into the ground, eliminating the necessity for an excavated trench.

Concrete envelope or monolithic construction is required for thin-wall nonmetallic conduits, such as fiber, transite and, in some instances, vitreous tile. This type of construction is necessary in the case of thin-wall nonmetallic conduits since they have limited structural strength and the concrete envelope furnishes the strength and protection for lasting qualities. The heavier types of conduit, such as precast concrete, steel pipe, and so forth are not usually built with an envelope. Monolithic reinforced concrete construction also is used in exceptionally poor soil or other unusual conditions where the conduit bank must have considerable strength.

If a watertight seal is required between the manhole and the conduit bank, there are several methods and materials available for making a satisfactory mechanical joint. The most common is probably to grout the conduit into the manhole wall. This provides a rather inflexible joint which is subject to cracking. A generally more satisfactory method is to use a sealing compound which adheres well to the materials involved and which does not harden to brittleness with age.

The conduit entrance or termination also should be designed so that the cable is not damaged by contact with the manhole wall or the conduit edge during pulling operations. Provision should be made to permit cable movement resulting from expansion or contraction of the cable without scraping the manhole wall.

Figure 6 indicates a method of sealing conduit entrances. The method used may depend on local conditions. If the manhole is in a normally dry location, watertightness may not be of particular importance. If the conduit section between manholes is short, expansion or contraction may not be too important. At any rate, the window for the cable as it leaves the manhole and enters the duct should be smooth, preferably bevelled. If it is designed to minimize damage during pulling, it will probably be satisfactory in so far as expansion or contraction of the cable is concerned. There are various devices on the market to make the conduit edge smooth. Most commonly used are precast duct bells of concrete or porcelain and conduit shields made of zinc or galvanized steel as illustrated by Figure 6.

Lubrication has the effect of nullifying to a large extent the difference in friction factors of various materials. It is general practice, however, to lubricate the cable sheath during the pulling operation rather than to attempt to lubricate the conduit system. Care must be exercised in the selection of lubricants for rubber or synthetic coated cables because of the deleterious effect of some oils and greases on these coatings.

The movement of the cables in the

Figure 12. Precast concrete conduit—change in elevation at manhole

Figure 13. Precast concrete conduit—offset at manhole

Figure 14. Single duct tile conduit encased in concrete

conduits caused by expansion and contraction is usually absorbed by the method of racking the cables in the manholes. In ordinary runs with moderate slopes, no difficulties will be experienced. However, if the slope of the conduit run is pronounced, the continuous expansion and contraction due to the heat cycles of the cable will cause the cable to creep into the lower manhole because the expansion of a cable due to its weight will always be downhill. Movement of the cable is generally prevented by installing grade clamps around the cable in the upper manhole.

Maintenance of Conduit Systems

In the design of a system, the possibility of future maintenance must of necessity be considered. This is particularly important in areas where damage might be reasonably expected as, for example, in a congested street or in unstable soil. Common methods of repair to conduits usually include the use of some type of split sleeve or adaptor for minor repairs without disturbing the cables. Major repairs usually mean rebuilding a portion of the installation and the construction is usually the same as that in building a new conduit system. Any repairs present the difficult problem of matching the repaired section to the existing section in that joints should be perfectly aligned to prevent damage to cable by sharp edges during their installation or withdrawal. Care must be exercised during a repair to be certain that backfill is properly placed in tamped layers to avoid the likelihood of uneven settlement taking place between a repaired section and the initial installation.

Services

Service conduits require the same considerations in selecting the material, size, and method of installation as does the main conduit system. In cases of large customers, the service conduits are often the same size, material and number as the distribution conduit system in the street. Residences, small customers, and street lamps, however, are usually supplied through one conduit. This single conduit may be of any material but it is not economical to install a conduit for this purpose that requires a concrete envelope. When selecting the conduit material, in addition to the usual considerations, thought must be given to the connections to the main conduit system and to the entrance of the conduit in the building or street lamp.

Connections to the main conduit system are usually made by diverting a conduit of the main system to a small manhole and running several conduits from this manhole to the buildings to be served. In isolated cases, adaptors are used to

Figure 15 (left). Multiple duct tile conduit

Figure 16 (right). Precast concrete conduit, distribution box, steel service pipe, and gas main

break into and tee off a main conduit in order to obtain a branch for a service connection. Figure 7 shows a typical adaptor. Where the building is set back from the property line, a small concrete box is installed at the property line for splicing the cable. The conduit into the building must be sealed or grouted around its outside surface to prevent water from seeping through the walls. The space around the cables inside the conduit also must be sealed for the same reason. Figure 6 shows a method of sealing the conduit.

Special Construction

Frequently such problems as unstable soils and bridge crossings necessitate modification of standard conduit design. In the case of bridge crossings, the usual difficulty is that there may be some movement of the bridge with respect to the roadway approaches or vice versa. This is likely to cause a failure of a conduit bank at the street junction with the bridge structure. The usual design in this case is to construct either a reinforced concrete conduit bank or to utilize steel pipe conduits to span the section from the bridge structure to firm soil off the bridge approaches, see Figure 9. The method of attachment of the conduits to the bridge structure obviously depends upon the type of the bridge. In some cases, it is possible to install conduits in the roadway or the sidewalk by spreading in a horizontal formation. In other instances, it is possible to support the conduits on hangers either beneath or on the side of the bridge. If a bridge is a steel structure and subject to appreciable expansion or contraction, the expansion joints such as shown in Figure 10 may be required.

When conduits are to be installed in unstable soil, the ideal design would be to have the conduit structure so built that it would accommodate itself readily to any soil movement. This frequently is not desirable from a point of view of maintaining cables. It may be necessary, in some instances, to support the conduit bank on pile bents. This requires the construction of a reinforced concrete slab of sufficient strength to carry the weight of the conduits and the superimposed live and dead loads for the span between the bents. Other methods utilized in poor soil conditions include the construction of either a reinforced concrete spread footing or a timber plank mat, see Figure 11. The purpose of this type of foundation is to reduce the unit load on the soil to a minimum and to insure if any settlement should occur that it would be of a uniform nature for the entire length of the conduit bank.

For installation beneath railroad embankments, busy highways or extensive lawns where open trenching might be inadvisable or impractical, conduits can frequently be installed by drilling methods.

Equipment is commercially available for drilling holes in excess of 100 feet in length and for diameters ranging from 2 inches to 24 inches.

Conclusion

The designer of a conduit system must be intimately familiar with both the electrical and structural problems involved. The time spent by competent personnel in planning is invariably repaid many times over by savings in construction, operation, and maintenance costs.

Discussion

E. J. Dawson (Commonwealth Edison Company, Chicago, Ill.): In this paper, Mr. Watkins has assembled general design considerations for the arrangement, location, and installation of conduit runs. The information presented will be of considerable interest to utility engineers embarking on a new underground program; also to underground engineers for comparison or review of their existing policies.

With this view in mind, the following comments are offered.

1. The length of a main conduit run may be maintained at a maximum, and intermediate service tap locations provided by the installation of a so-called service-type manhole. This is a narrow structure built to include the conduit along one wall. The top horizontal row of ducts, which by policy contain the secondary main cables, are omitted or broken out, permitting the main cables to be exposed in the manhole for service tap connections.

2. Although longer lengths of individual conduit pieces are desirable for more economical handling and better alignment of ducts, their limitations in congested areas should be recognized. Shorter conduit lengths are of value in obtaining large radius sweeps in the run and for splitting layers of ducts above and below service pipes of other utilities. When such curvature is included in a run, the cumulative angular displacement should be limited to an amount consistent with permissible cable pulling tensions.

3. Conduit capable of being split longitudinally on the job is of value for use in swinging an existing conduit run containing cables into a new manhole, for enclosing new lengths of cable that are field duct spliced to existing cables, or for piecing out a conduit run through a manhole that is being abandoned. A precast concrete conduit which can be split along two longitudinal V-shaped grooves on opposite sides is manufactured for this purpose.

4. Under the subcaption of Figure 6 was the statement that both ends of conduits between manholes or vaults should be sealed. This practice may cause serious corrosion of the lead sheath of cables if the conduit is encased in concrete. Ground water seeping through the concrete will react with the uncombined free lime in the cement to form calcium hydroxide. With the conduit sealed at both ends, the alkalinity of the solution will increase to the strength where the lead will be attacked. To reduce this action, only one end of the run should be sealed, preferably at the building or vault wall, and the conduit sloped from this end to the line manhole. In this way, sewering of the manhole or occasional pumping for construction work will drain the ducts, thus preventing trapping of seepage water.

5. As mentioned by Mr. Watkins, it is usually advantageous to slope conduit runs to drain to a manhole. However, existing underground equipment may sometimes necessitate installation of a new conduit run below such equipment. To avoid excessive cost of continuing at a low elevation to the next manhole, the conduit may be brought up to normal elevation, and the corrosive possibilities of the resulting sump eliminated by either one of two methods: Neoprene jacketed lead covered cables may be installed in this run; or a drainage gap, employing fiber or transite conduit having drilled drainage holes is installed across a gap left in the concrete sheathing at the low point in the run. Drainage may be obtained to either a gravel basin or municipal sewer.

6. One method of installing conduit not mentioned in the paper is that of pushing steel conduit through the ground by means of a hydraulic jack. This method has been successfully employed at street or railroad crossings to eliminate traffic problems or costly box tunnel construction work. This procedure is, of course, limited to 1-, 2- or 3-duct installations in earth where the presence of boulders or the equipment of other utilities is not anticipated.

W. A. Del Mar (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): Figure 5 does not take into account the radius of curvature of bends, an important factor in determining the equivalent length to be added for friction at bends. The friction coefficient of 0.6 seems to be extraordinarily high. Values around 0.4 are more usually found for duct lines.

E. G. Driscoll (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): Figure 5 of the paper contains an error which may or may not be of much consequence, depending on the dimensions of the bend in relation to the straight run. It represents the equiv-

alent length at the exit from the bend as a straight line function of the length at the entrance to the bend. No consideration is given to the length of the bend itself and this omission introduces an error.

The general equation for the condition under consideration, based on belt slippage on a pulley, is:

$$L_1 = e^{Ka}(L + Ra)$$

a = angle subtended by curve in radians
e = base of Naperian logarithm
K = coefficient of friction
L = equivalent length at entrance to bend in feet
L_1 = equivalent length at exit from bend in feet
R = radius of curve in feet

In order to represent this relation as a straight line it is necessary to plot the equivalent exit length against the quantity $L+Ra$, not against L alone. The present error can be eliminated by stating the ordinate to be "Equivalent Length at Entrance to Bend Plus Length of Bend."

Robert J. Wiseman (The Okonite Company, Passaic, N. J.): This paper presents in a clear yet brief manner the various factors that must be considered when designing duct systems for the transmission and distribution of electric power. One readily notes that it is not a haphazard, hit or miss proposition, but a highly technical engineering problem involving many factors as listed under the section on Design Considerations. With the increase in the use of the streets, a design of a duct line becomes quite a problem and costly. Therefore, everything possible that can reduce costs yet maintain high efficiency must be done. Table I of the paper shows how the various materials that may be used affect the design. Figure 3 shows how the shape of the duct structure influences heat dissipation, yet we do not consider it when we calculate the thermal resistance of the duct bank and surroundings. We take the same duct heating constant whether the ducts are laid up to give the best ability to radiate heat or the poorest. With the desire today to get every ampere of load possible out of a cable it appears that we will have to abandon the use of the present duct heating constants and set up new ones which take into consideration the duct formation. This can be done as we already have had a paper on heat dissipation from underground systems.[1]

We all know the importance of cable movement on the life of a cable and how necessary it is to properly train the cables in the manhole to prevent sheath cracking. Snaking of a cable in a duct bank also is helpful. Where the duct has curves in it, it helps snaking. Has the author ever considered actually putting a wave in a duct run even though it could have been installed straight to help out the snaking?

Costs of duct systems are constantly rising which makes it necessary to consider direct buried cables, although in some instances the flexibility of the latter is not good. Could the author give us an idea of what costs might be today as compared to pre-World-War II?

C. S. Schifreen (Philadelphia Electric Company, Philadelphia, Pa.): This paper contains a good qualitative check list of fundamental design considerations, but we believe it is inadequate in the author's treatment of pulling friction and of the corrosion characteristics of conduit materials.

The derivation of his Figure 5 uses a coefficient of friction so high that it could be representative only of cable installations made without the use of any lubricants whatever. We also infer that the 600-foot maximum length suggested in his discussion of this figure is based upon a disregard of the advantages of pulling lubricants. We think that the use of such lubricants is a fundamental design consideration which has not been evaluated by the author. Our laboratory tests on 100-foot lengths of 69-kv single-conductor 1,500,000 circular mil and 15-kv 3-conductor 350,000 circular mil paper and lead cables in straight $4^1/_4$-inch tile ducts developed an average friction coefficient of 0.27 when using customary cable pulling lubricants. The averages were 0.30 for starting and 0.24 for sliding friction. The author's failure to account for lubrication therefore unreasonably reduces the maximum allowable pulling length. Present standard practices in the Philadelphia Electric Company authorize 1,000-foot maximum lengths in conduit sections having bends of not less than 500-foot radius. Our maximum pulls to date have been upwards to 800 feet of 69-kv single-conductor 1,500,000 circular mil and 15-kv triplexed 500,000 circular mil paper and lead cables in typical runs of $4^1/_2$-inch fiber and $4^1/_4$-inch tile ducts and have been accomplished with no difficulties.

The corrosion problem was very carefully reviewed before authorizing the use of fiber conduit in Philadelphia, and does not support the author's evident conclusion, Table I, that tile duct is preferable to fiber from the corrosion point of view. Field surveys of corrosion exposures have shown consistently that fiber conduit encased in a concrete envelope interposes a much higher coupling resistance between the lead sheath and its environment than is found in comparable installations of concrete-encased tile. In our evaluation of the relative merits of conduit materials we have given weight to this quality of fiber conduit only in situations where other things were equal. For the purpose of this discussion, however, it is sufficient only to point out that the corrosion characteristics of fiber conduit are at least equal and, under average conditions, superior to those of any other conduit material.

E. G. Watkins: It was intended and hoped that this paper would present the fundamentals and basic principles which might serve as a basis for the design of an underground electric conduit system. No attempt was made to discuss construction practices in detail. Obviously, there are many such practices in common use of which no mention was made.

The author's company has had experience in obtaining friction coefficients as low as those mentioned by Mr. Schifreen. Figure 5 was presented as an illustration of a tool for determining the length of conduit sections. The curves do take into consideration the lengths of the bends; they are specific for radii between 3 feet and 20 feet. Since our data indicate that within limits the angle of the bend is the most important factor rather than the radius of the bend, the curves are useful for radii exceeding 20 feet. The equation for these curves, as developed by the engineers of the Consolidated Edison Company, is:

$$L_2 = L_1 \cosh F\alpha + \sqrt{L_1^2 + \left[\frac{R}{F}\right]^2} \times \sinh F\alpha$$

where

L_1 = the equivalent length at the entrance to the bend
L_2 = the equivalent length at the exit from the bend, including the length of the bend itself
F = the pulling coefficient of friction
α = the angle of the bend in radians
R = radius of bend

Terminal Risers for Solid-Type Impregnated Paper Cables

W. A. DEL MAR
FELLOW AIEE

TERMINAL risers for impregnated paper cables have long presented a problem to utility engineers because of the diverse operating results reported. In one place trouble would be reported on risers about 15 feet high, and yet in another place risers three or four times that height gave no trouble.

The Insulated Power Conductors Committee undertook a study of this situation, and the present paper presents the views of the Subcommittee* charged with this task. The scope of this study is confined to pole, terminal tower and station risers, and is not intended to include distribution risers in tall buildings, mine cables, or other extreme cases. It covers only solid-type paper-insulated cables. No attempt has been made to cover varnished cambric or rubber-insulated riser cables, although these are used occasionally.

The problem stated in terms of physics, is to maintain intact a group of parallel capillary columns of viscous oil. These columns, in a new cable, lie in the interstitial edge spaces of paper and metallic tapes, in the interstrand spaces of conductors, in the irregular spaces in the fillers, to a less extent in the flat spaces between tapes, and to an almost negligible extent between the fibers of paper. In a cable which has been subjected to severe load cycles, the most important columns of oil are in the spaces directly under the lead sheath. Each of these columns of oil may be likened to a modified barometric mercury column. Consider a closed-top glass tube, say 40 inches high, standing in a trough of mercury. If the tube had been filled with mercury before it was inverted over the trough, the mercury in the tube would drop to, say 30 inches above that in the trough, leaving a vacuum above. If, however, instead of an open trough, we had a closed metallic vessel completely filled by the mercury, atmospheric pressure could no longer balance part of the mercury column, and the sides of the closed vessel would be subjected to an internal pressure due to the entire 40 inches of mercury. Let us now consider a third case, where the trough is replaced by a closed rubber vessel. Here we have three evident forces at work; the weight of 40 inches of mercury is opposed both by the weight of the atmosphere and by the elastic tension of the rubber vessel as it is stretched by the weight of mercury. In this case the mercury will not sink to the 30-inch level, but to some higher level, depending on the stress in the rubber walls. The last case is analogous to the capillary oil columns in a vertical cable, the lead sheath acting somewhat like the rubber walls of the vessel in our imaginary model.

Let us first consider the case of an unloaded or lightly loaded cable. The forces at play are the weight of the oil column opposed by the hoop stress in the lead. There also is a small force assisting these two, due to the surface tension at the top of the column of oil, but we may neglect this, for the present. The hoop stress in the lead is proportional to the difference between the hoop pressure due to the atmosphere and the hoop tension due to the weight of the oil column. These are equal and opposite when the oil column is about 35 feet high; but when it is over 35 feet, the hoop stress becomes a tension corresponding to the excess of the height over 35 feet.

A normal sheath of copper-bearing lead is able to carry a hoop stress corresponding to an internal gauge pressure of about one atmosphere. This is the principle upon which low gas pressure cables operate. Therefore, under ideal conditions, such a sheath should support a riser of twice the barometric height, that is, 70 feet.

If absolute reliance could be placed on the gas-tightness of every pothead, and if other conditions were ideal, including light current loading, there would be no riser problem for heights up to 70 feet, but experience has shown that with the best control of workmanship, absolute gas tightness cannot be relied upon where large numbers of potheads are involved. It is, therefore, customary to assume the possibility of slow leaks and design accordingly. The unpredictability of slow leaks accounts for some of the operating discrepancies noted. Such leaks are not necessarily the result of poor workmanship by linesmen, but may be due to porosity of materials used. However, in special cases, such as station risers, where particular care can be given to making the potheads tight, design may be based on the assumption that the hydrostatic pressure results only from the head of oil in excess of the barometric height. This is subject to the limiting condition that the pressure due to head is not augmented by expansive pressure of the oil sufficiently to exceed the permissible hoop stress in the lead.

Some of the early troubles with short risers were traced to the use of a type of pothead which did not terminate the

Paper 50-258, recommended by the AIEE Insulated Conductors Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 27, 1950; made available for printing September 12, 1950.

W. A. Del Mar is with Phelps Dodge Copper Products Corporation, Yonkers, N. Y.

*The Subcommittee, over the several years this subject was studied, included the following members: Wm. A. Del Mar, Chairman, E. D. Best, C. T. Hatcher, M. H. McGrath, J. H. Neher, G. B. Shanklin, F. V. Smith, R. J. Wiseman, M. Ghen, R. K. Woodson, and D. M. Farnham. Many paragraphs of this paper, as well as the appendixes, are due to one or other of these committee members. Mr. Homer Martin also contributed useful data. Appendix I was written by M. Ghen; Appendix II by R. K. Woodson; Appendix III by D. M. Farnham; Appendix IV by W. A. Del Mar; Appendix V by C. T. Hatcher; and Appendix VI by Homer Martin.

cable conductors but carried the bare or insulated conductors through the top. Air and moisture penetrated into the cable through the strand spaces and led to failure. Other trouble occurred when thinner insulation was introduced, giving rise to higher stresses and more intense ionization where the level of oil had fallen due to stretching of the lead by oil expansion.

Considering the case where absolute gas-tightness of the pothead cannot be relied upon, the critical height due to head of oil may be calculated from equation 1.

$$\text{Critical height, feet} = \frac{5PT}{D} \qquad (1)$$

where

P = permissible hoop stress, usually taken as 125 pounds per square inch for plain lead, 150 pounds per square inch for copper-bearing lead, and 175 pounds per square inch for arsenic-alloy lead
T = thickness of sheath, inches
D = internal diameter of sheath, inches

For heights below the critical value thus established, no special precautions are ordinarily required in northern climates, for lightly loaded cables, but for greater heights, or heavily loaded cables, one or other of the expedients subsequently described is ordinarily adopted. Experience indicates that in the South, the critical height of risers is, in general, less than 35 feet. The comparison of a cable to a modified barometer would be substantially true for an oil-filled cable, that is, with sizable oil channels and oil of low viscosity, provided that the loading of the cable is light.

When a completely impregnated solid-type cable is first installed, it can be conceived of as an oil-filled cable without voids but with longitudinal oil feed channels of extremely high flow resistance. Due to the high viscosity of the oil and the extremely small feed channels, the restriction to longitudinal flow of oil is thousands of times higher than that in an oil-filled cable. The surplus oil in those small channel spaces is not held back completely by capillary attraction, as is the useful oil in the compact insulation, but responds very gradually to gravity. Head pressure will eventually be built up at the base of the riser, after which a ratcheting effect will occur if temperature is suddenly raised by load or otherwise. Longitudinal restriction to flow is so great that the expansion pressure cannot be fully relieved by a return of compound towards the top. This means that the transient expansion pressures are superimposed on the slow, steady build-up of gravity head pressure, and if the total pressure at the base exceeds the creep strength of the sheath, stretching will occur and it will be cumulative unless this condition is relieved. Obviously, any lead sleeve joint near the base of the riser must be reinforced or a more rapid and concentrated swelling will occur at this point.

Compound migration in solid-type cable is primarily due to a pressure differential along the length of the cable, whether caused by gravity or other agency. A striking illustration of this is the behavior of nonreinforced lead sleeve joints on grades. When such solid-type cable lines are heavily loaded, there is a tendency for swelling or collapsing of these lead sleeves simply because they are the weakest link in the chain. A study of such happenings shows that the sleeve swelling is rarely related to profile and gravity drainage. Sleeve swelling can occur on level ground or at the tops of grades just about as often as at the bottom of grades. This is primarily due to two factors. First, the joints are far apart and gravity drainage through the highly restricted longitudinal "feed channels" is so slow that it cannot respond in any great length of cable and is only pronounced on extremely steep and short slopes or in vertical risers. Second, a pressure increase uphill must mean a pressure differential in this direction, tending to push the compound uphill, and this is due to a difference in temperature and compound expansion (or shrinkage) along the length of the line, caused by thermal variations along the length. If the line is hotter downhill, pressure builds up and tends to push the compound uphill towards the cooler portion, or towards a portion that has previously drained and has low pressure.

In short vertical risers, gravity drainage is a more important factor, but reverse pressure differential also can occur in vertical risers due to the fact that there is a much wider temperature variation in the exposed vertical length as compared with a horizontal underground length. However, even with a sunlight temperature of 50 degrees centigrade, riser cables are usually 5 to 10 degrees cooler than duct cables. Night and day temperature variations, wind, rain, snow, and seasonal variations all tend to set up such differential pressures and make the behavior somewhat unpredictable. This does not occur in oil-filled cable because the response to gravity drainage is too quick. The net result is that under some conditions excessive pressure can be built up at the base of the riser, and under other conditions it can be built up at the top of the riser, tending to start leakage in the potheads.

Heights Above Critical

For heights above the critical, or where loading adds appreciably to the pressure, three classes of measures have been used to overcome migration.

1. Where Measures Are Directed to Preventing Vacuum Formation Above the Critical Height

(a). A highly viscous oil is used in the pothead which can seep into the vacuous space below the pothead, but is so viscous and has such high adhesion or surface tension that it adds little to the head of oil.

(b). This type of construction has operated successfully on a 22-kv system for eight years, the risers of an average height of 50 feet. A number of them operate at full load even during the hot summer months, but the average load on the risers is 50 to 80 per cent of the cable rating. A simple semistop joint is used in the manhole at the base of the riser, see Appendix I.

Figure 2. Block and clamp for riser cables

2. Where Measures Are Directed to Preventing Excessive Strain of the Lead

(a). Reinforcement of the lead sheath by bronze or coated glass tapes. An installation of seven solid-type 66-kv riser cables 75 feet high on steel poles has been operating for 19 years. The riser cables have double lead sheath with bronze reinforcement, gravity feed reservoirs at the top and stop joints at the bottom. Wooden supporting clamps (without cushions) are credited with stopping migration between sheath and insulation, see Appendix III.

(b). Use of clamps with rubber cushions to prevent oil migration between sheath and underlying layer. Risers approximately 30 feet high, with plain lead sheaths on wooden poles, were originally supported by galvanized iron straps with 1/8-inch lead lining. Vibration led to intercrystalline fracture of the lead. These clamps were replaced by wooden clamps with rubber cushions which have proved satisfactory, see Appendix II.

3. Where Measures Are Directed Both to Preventing Vacuum Formation Above and Excessive Head Below

(a). Reservoir of cable oil at base of pothead and reservoir at joint nearest to base of riser, the oil which has dripped into the lower reservoir being periodically restored to the top reservoir, see Appendices III and IV.

(b). Use of a partially drained cable with 12-pounds-per-square-inch nitrogen gas pressure applied to the cable near the top. This also requires a reservoir to receive oil which may subsequently drain, see Appendix V.

When Each Type of Construction Is Advisable

Constructions described under section 1 should not be used without due consideration to the possibility of sheath stretch and bursting of joint sleeves below the riser, especially when high operating temperatures are attained.

Construction described under section 2 should not be used without due consideration to the possibility of vacuum or air pocket formation at or below the base of the pothead and, where necessary, providing protection against this possibility either by the means described under section 1 or by using thin oil in the pothead and a reservoir of thin oil attached thereto. Ordinary clamps should not be used, however, where the structure to which the cable is attached is subject to much vibration. Wood poles with aerial wires are subject to severe vibration. A special cushioned clamp, described in Appendix II, overcomes this difficulty. See also Appendix III.

Constructions described under section 3 are the most reliable, although the most expensive. They are particularly desirable in the Southern states where long periods of high temperature aggravate conditions.

Types of Cables

Due to the smaller diameter and consequently greater critical height of single-conductor cables, as compared with 3-conductor cables, it is desirable to trifurcate at the base of the riser, using a trifurcating joint and to rise to the potheads with single-conductor cables. While this is usually practicable for station risers, it is not always practicable for pole risers in streets.

Drainage is more severe with shielded than with belted cables. However, if the usual bronze binder is replaced by a belt of paper, shielded cables suffer less disadvantage.

Joints

The joint at the base of a riser should be more or less of a stop-joint. A practical construction has blocked connectors covered with oil-silk sealed with oil-insoluble material, such as Harvel oil-stop, Vinsol resin, or Minerallac and castor oil, varnished cambric insulating tape, and oil-insoluble solid-type compound where a reservoir is not to be attached. If a reservoir is to be attached, a fluid oil compound must be used. In either case, the joint should be shielded throughout, if the cable is shielded.

Cables with Viscous Compounds

Some utilities have used riser cables impregnated either with petrolatum or a viscous stringy compound containing a highly polymerized oil derivative. Petrolatum has a melting point of about 55 degrees centigrade, and above that temperature is less viscous than ordinary oil impregnants. If, therefore, viscosity is the desired characteristic, it is attainable with petrolatum only if the operating temperature of the cable is kept very low. Viscosity, however, does not inhibit migration of compound; merely makes it slower. A more desirable characteristic would be high surface tension, but the available range is quite limited. A stringy adhesive cable impregnant has more merit for delaying migration, but it is not a cure and is open to the objection that it requires special cable which does not have the best electrical characteristics, yet is apt to be very expensive due to unusual manufacturing requirements.

In view of the complications and the varied behavior involved, it is not possible to be guided by calculated head pressure alone, as is the case with oil-filled cable. Such calculations throw some light on the problem and help in reaching a clearer understanding, but the ultimate answer must be based on actual field experience in different localities and climates and under different conditions of loading. Due, however, to the many factors entering into the problem, records of field experience are contradictory and confusing. The data required for a complete study of a riser cable are listed in Appendix VII. Therefore, we end our study with the unsatisfactory conclusions that both theory and recorded experience are unreliable guides and this paper is, therefore, not an effort at standardization, but a presentation of the subject as known to us, and an invitation to bring broader experience to bear on the problem.

Appendix I. 22-Kv Cable Terminals—Viscous Compound Filled*

The Duquesne Light Company, Pittsburgh, Pa., has successfully operated viscous compound filled cable terminals on its cable system for the past eight years.

Ten years ago their terminal pole construction was changed to a 3-way multiple

* Example of case cited in section 1(b).

Figure 3 (left). AC reservoirs. Characteristic curves at various temperatures

Res. Size Gallons	No. of Cells	Res. Size Gallons	No. of Cells

joint in the manhole with single-conductor cables from manhole to the cable terminals instead of 3-conductor pole risers with the "Y" joint on the terminal pole, but no change was made in the method of installing the cable terminal. Cable failures on terminal poles began to occur more frequently, and in most cases the cause could be assigned to cable impregnating compound migration, because of the lighter oils used in new cables. To overcome this problem of loss of cable impregnating oils in the cable insulation, the filling compound for cable terminals was changed to a mineral oil compound similar to that used in impregnating the cable insulation.

Several failures were soon experienced in the new construction; therefore, it was necessary to conduct special tests to determine construction standards for cable terminals. These tests and results were discussed in a paper made by W. P. Cook before the Thirty-first Meeting of the Transmission and Distribution Committee of the Edison Electric Institute on May 10, 1943. Our present standard is practically the same as shown in the above-mentioned paper, the only major change being in the compound. During the past five years, we have experimented with various compounds and at present our standard is 80 per cent cable oil and 20 per cent polyisobutylene.

The Duquesne Light Company has approximately 400 22-kv risers on their system of which approximately 300 (900 potheads) are now viscous compound filled. They are installed on both single-conductor and 3-conductor cable, with single-conductor as their present standard, and have operated successfully at 22 kv over a period of eight years. The maximum height of any riser on the system is 80 feet, with the average being approximately 50 feet. (The 80-foot riser has a special tacky oil.)

Sheath bulges were expected at the bottom of the risers originally, but operating experience to date has shown none. However, present standard construction is an oil stop joint in manhole at the base of the riser: three layers of silk tape, each layer basted with an oil-insoluble compound, are applied to each conductor prior to the application of the varnish cambric insulation and the joint is filled with a hard, oil-insoluble compound. A barrier-type connector is used to prevent compound migration through the strands. The riser cables are not clamped to stop migration between the sheath and core; so far it has not been found necessary.

No checks were made on the actual operating temperature of these risers; however, a number of them operate at times at full load rating even during the hot summer months. A large per cent of risers feed the overhead system in comparatively lightly loaded areas where the emergency load ratings automatically limit maximum daily loads. The average load of the risers is 50 to 80 per cent of the cable rating.

An inspection of terminals is made approximately once each 3-year period. In most instances, the compound dropped on an average of one pint in the terminal at the first inspection; the second inspection usually shows a decrease in the loss of compound. In no instances have more than two inspections been made to date. Internal flashover due to a vacuum in the terminal is not feared inasmuch as the use of a 46-kv terminal on the 22-kv system due to external contamination, and the over-all length of the porcelain is sufficient to prevent such an occurrence.

There are two essentials which we feel are necessary for successful operation of oil-filled cable terminals:

1. Absolutely tight seals on gaskets and wipes. Glyptal lacquer is used to cover joints.
2. Proper lightning protection by installing the lightning arrester on the same arm with the cable terminal.

To sum up the problem, it is not believed feasible to operate oil impregnated cables as pole risers without provision for keeping the cable saturated throughout its entire length. This applies especially to the portion of the cable within the base of the terminal. Even though this type of system appears to operate successfully in Pittsburgh, Pa., the author would be reluctant to recommend such a system for localities subjected to much higher summer temperatures.

The viscosity of the compound used on this installation was as follows:

Deg. F	Saybolt, Seconds
100	7,200
140	2,030
212	397

Appendix II. Operation of Cables on Wooden Poles—Kansas City Power and Light Company

Paper-insulated lead-covered cables are used as pole risers on the 13.2-kv and 4-kv system in this company. The majority of the 13.2-kv risers are of 400,000-circular-mil shielded type, while the 4-kv risers, as discussed here, have been mostly of 3/0-4-conductor belted construction.

Iron lateral pipes are installed from ground level up to the height specified in the National Electric Safety Code.[1] These are attached to the pole with perforated pipe strap and spike nails. A wooden block, bored to the cable size, is used on top of this pipe. The cable is attached to the pole at 3-foot intervals above the pipe to directly below the bend leading to the multiconductor "Y" shape pothead.

Prior to 1941 considerable trouble was encountered with crystallization of the lead sheath at the pole blocks which were galvanized iron straps with only a 1/8-inch lining of lead between strap and cable. This was definitely traced to vibration of the poles.

Figure 4. Constant volume oil reservoirs for cable joints

1—Oil setting 40 per cent

2—Gas pressure indicated on each curve as at specified oil setting

At that time a cushion type of clamp, shown in Figure 1, was developed and has eliminated all trouble from that source.

The most effective example of the value of this cushion is a pair of cable replacements on *1527-2* terminal pole. This cable of 400,000-circular mil 3-conductor 15-kv belted construction was installed on the pole in 1936. This pole was one of the two pole structures carrying a lightning arrester rack, platform disconnects, and so forth. The pothead is approximately 30 feet above ground. The structure is dead end one way and no side guys are used. On April 28, 1935, the sheath was found to be crystallized at three clamps and the cable was replaced. Again, on October 30, 1940, the same condition was found, a new section of cable was again installed. Rubber cushions were used in the blocks on this installation, and no further trouble has developed.

The system contains approximately 261 cables terminating on wood poles. Between 1929 and 1942 ten sections of cable are known to have been replaced due to "crystallized" lead, while eight other sections *may* have been replaced due to this trouble from 1920 through 1923, and in the year 1939. The records are not too good on this point. Since the advent of the rubber cushions, no further trouble has developed.

Appendix III. Risers with Wooden Clamps—Quebec Hydroelectric Commission

There are 13 66-kv cables, each approximately 4,000 feet long, running from steel poles at the foot of St. Lawrence Boulevard to Vallee Substation. The cables are all single-conductor, 750,000 circular mil stranded copper, paper-insulated, 0.003 metallized paper tape and 9/64-inch lead sheath.

Seven of the cables are nonhollow core and have an insulation thickness of 28/32 inch. The other six are hollow core and have an insulation thickness of 30/32 inch; these six were impregnated with rosin-bearing compound, in general of the type used in 1926.

The end lengths of the cables from the end manholes to the substation and the steel poles are specially reinforced. For the nonhollow-core cables the reinforcing over the insulation consists of: 0.008 metallized paper tape, 0.125-inch plain lead, 0.005 phosphor bronze tape, one layer of paper and 0.100 plain lead over-all. For the hollow-core cables, the reinforcing is obtained by using lead with 0.5 per cent antimony instead of plain lead.

At the steel poles and at Vallee Substation the cables terminate in oil-filled outdoor-type terminals rated at 110 kv.

The joints in the cable lines are oil-filled and connected to oil reservoirs to maintain positive oil pressure. The hollow-core cable terminals have their own glass reservoirs mounted on the terminal tops, while the nonhollow-core cable terminals are fed from gravity-type reservoirs.

The cable risers on the steel poles are mounted and supported as shown in Figure 2, and while the wood block clamps were originally placed there to adequately support the cable, it is felt that they have served as sheath clamps to prevent the migration of oil or compound between the lead sheath and the cable insulation.

Experience from 1926 to date has been extremely satisfactory as far as the riser cables are concerned and, in the main, this is attributed to the fact that there has been very little compound migration. The nonhollow-core risers were manufactured in 1931, and the compound in these is the cylinder oil class. When they were installed, transformer oil was fed into the strand of the cable at the upper end of the riser and allowed to run through to the lower end, thus washing all compound out of the strand to permit the free passage of oil. The end lengths were then connected to the horizontal runs through stop joints. The height of these risers is about 75 feet.

Appendix IV. Reservoir Systems for Impregnated Paper Insulated Riser Cables

General

The reservoir system for impregnated paper-insulated riser cables provides a method for eliminating the troubles ordinarily caused in such installation by downward migration of the impregnating compound. Briefly, the method consists of allowing a slow continuous flow of oil through the cable, from top to bottom, by feeding viscous cable oil into the splice at the top of the rise and draining it from the splice at the bottom. This prevents the building up of high internal head pressures at the bottom of the rise with attendant stretching of the lead sheath, and also avoids desaturation of the insulation at the top of the rise with accompanying loss of desirable electrical properties.

The arrangement requires a reservoir at the top of the rise which supplies oil to the system as required, and a reservoir at the bottom of the rise into which oil is drained to relieve excess pressure.

This system may be used either with constant volume reservoirs in which the oil is in contact with nitrogen gas or with bellows or cell type reservoirs in which the oil and gaseous pressure medium are separated by metal partitions. In the former case, identical reservoirs are used at top and bottom of the rise. In the latter case two different types of reservoirs are used, as described below. The operations are identical for the two types of reservoirs except that the constant volume reservoir at the top is maintained at a minimum of 1 pound per square inch and preferably several pounds per square inch nitrogen gas pressure, whereas the top bellows type reservoir, type *CC*, remains at atmospheric pressure.

A type *CC* reservoir contains cable oil in a stack of collapsible cells immersed in transformer oil. The amount of oil in the cells is indicated by the sight-glass level of the transformer oil outside the cells. Type *AC* reservoirs, which are used at the foot of riser, also contain collapsible cells, but these cells are filled with gas under pressure and sealed at the factory. The cable oil is contained in the tank *exterior* to the cells. Characteristic pressure curves for these reservoirs are shown in Figure 3.

Viscous cable oil is used in the system. If thin oil were used, it would soon wash out the original oil of the cable and require an excessive frequency of servicing to keep the pressure in the *AC* reservoir below the safe limit. With the viscous oil, the frequency of servicing will be high at first, but will soon

Figure 5. Constant volume oil reservoirs for cable joints

1—Oil setting 50 per cent
2—Gas pressure indicated on each curve as at specified oil setting

Figure 6. Constant volume oil reservoirs for cable joints

1—Oil setting 70 per cent
2—Gas pressure indicated on each curve as at specified oil setting

settle down to a practical value. During the first few weeks after installation, therefore, the system should be watched carefully, but after the oil flow has reached a steady state, servicing will be required probably but once or twice a year. Servicing involves the operations described below.

Reservoir at Bottom of Rise

The oil pressure at the center line of the lowest joint at the bottom of the rise should not be allowed to exceed 10 pounds per square inch. This pressure may be determined by the gauge on the manifold by using the following formula:

Pressure, pounds per square inch at center line of joint = gauge reading $+0.4B$

where

B = difference in elevation in feet between gauge and center line of joint

When the pressure approaches 10 pounds per square inch, oil should be drained from the reservoir until the pressure at the center line of the highest point fed by the reservoir is 0.5 pound per square inch. This pressure may be determined from the gauge reading by means of the following formula:

Pressure, pounds per square inch at highest point = gauge reading $+0.4A$

where

A = difference in elevation in feet between highest point and gauge

If necessary, add cable oil to bring the pressure up to at least 1 pound per square inch, using a hand-operated pump in the case of an *AC* reservoir or a cylinder of nitrogen gas in the case of the constant volume reservoir.

Reservoir at Top of Rise

In the case of the *CC* reservoir, the oil level as shown by the sight glass on the reservoir should not be allowed to fall below 0.5 gallon. When this limit is approached, it is necessary to add oil. Using the hand-pressure pump, add cable oil until the sight glass shows the reservoir to be filled to one gallon less than its rated capacity. In the case of the constant volume reservoir, two outlets are provided and a measuring rod is provided which is inserted in the lower outlet. Here again the level should not fall below 0.5 gallon.

Appendix V. Gas Pressure and Oil Tank Method*

The use of this method was decided upon in connection with attempting to reduce the migration of the joint filling oil in the street cables adjacent to river tunnel crossings. This joint filling oil was found to be migrating down the vertical riser cables and into the tunnel portion of the cable, creating an excessive pressure and consequent bursting of the joint sleeves. These vertical riser cables have a drop of approximately 50 feet. It was decided to experiment with the use of nitrogen gas pressure at the upper end of the riser cable on one particular feeder. This riser cable was installed in 1931 and is a 3-conductor, 350,000-circular-mil shielded-type construction with 345 mils paper and 125 mils lead. The diameter under the lead sheath is approximately 2.85 inches. This cable operates on a 27,000-volt neutral-grounded system.

A 10-gallon reservoir was connected to a stop joint at the top of this riser and filled with nitrogen gas at a pressure of 8 pounds per square inch. A stop joint also was installed at the lower end of this cable, with similar oil reservoir attached. This installation was made in 1938, and the reservoirs have been inspected approximately twice a year since this time. The pressure in the upper reservoirs has been found to have dropped to as low as 3 pounds per square inch at some inspections. The pressure was raised to 8 pounds per square inch at every inspection.

Appendix VI. Servicing of Constant Volume Reservoirs

In using constant volume gas pressure reservoirs (Appendix V) particular attention must be paid to initial and servicing settings of oil and gas and also to the amount of oil returned in relation to "built-up" pressure resulting from such quantities of oil flowing back into the reservoir.

The curves listed in Table I were developed to facilitate both the instructions for the setting of this oil line and gas pressure, and also in selecting the proper positions of the various fittings in the shell of the horizontal reservoir.

*Method given in section 3(b).

Table I

Curve	Oil Setting (Levelling Fitting Location)	Setting
Fig. 4	40% level* (tank cap.)	40% oil, 8#
		10% oil, zero #
		30% working oil
Fig. 5	50% level	50% oil, 8#
		22% oil, zero #
		28% working oil
Fig. 6	70% level	70% oil, 8#
		53% oil, zero #
		17% working oil

*The 40% level will permit the quoted range of usefulness for riser cable application.

Appendix VII. Schedule of Data Required for Complete Evaluation of Experience with a Riser

1. Height of riser from base of pothead to lowest part of cable.
2. Distance (along cable) from base of riser to nearest joint.
3. Description of cable.
   Conductor compact or uncrushed.
   Number and size of conductors.
   Thickness of individual tapes.
   Total thickness of insulation.
   Shielded or belted.
   Type of binder tape.
   Thickness and type of lead.
   Cable diameter under lead.
   Viscosity of impregnant over operating range or year and name of maker.
   Reinforcement, if any, over sheath.
4. Type of supporting clamp, if any.
5. Range of ambient temperature.
6. Range of load.
7. Type of pothead and opinion of its gas tightness.
8. Type of pothead compound.
9. Pertinent conditions noted.

Discussion

E. W. Greenfield (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): The analogy of a lead-sheathed cable to a rigid tube having an expansible rubber membrane at the bottom probably is an over-simplification of the case. Instead, it seems reasonable that a riser cable is more likely a tube closed at both top and bottom with rigid sections, the tube walls being of a relatively high-strength elastic material.

The two analogies operate quite differently. In the first, as long as the top of the column is tight, the tube at its base will be compensated in pressure to the extent of that exerted by the atmosphere; namely, 15 pounds per square inch, or a total height of oil of about 35 feet. This does not agree with known facts. Actually, when pressure is applied externally to a tube, a considerable drop occurs across the circular rigidity of the tube. When sufficient pressure is applied, it is found that the sheath tends to crumple rather than to compress inward uniformly. For example, in a gas compression cable, when 200-pound-per-square-inch pressure is applied externally, a pressure drop through the lead diaphragm of 30 to 40 pounds per square inch may occur. On the other hand, pressure applied internally subjects a round sheath to continuous motion in the form of creep once the critical value is exceeded. For common lead, this critical value is quite low. Another factor preventing the cable from operating in accordance with the assumed analogy is that no impregnation is absolutely perfect; accordingly, some oil always will be displaced downwards. The net result is that a riser installation with perfectly tight potheads can still exert sufficient pressure at the base of a 15-foot riser to cause sheath deformation. Added to this, the effect of load cycling is to immediately create more space between core and sheath for further drainage in these areas.

I believe that the author underestimates the forces of adhesion in his analysis of the migration problem. Whereas the surface tension forces in capillarity action operate

only at the top of the column, the forces of adhesion are active throughout the column. These forces have to do with the molecules in the liquid and in the column walls and also are dependent upon temperature. For small columns, adhesion can overcome completely the effects of gravity. The degree to which this occurs, however, must be related to the temperature.

We agree with the author that, in a low-pressure gas-filled cable, the oil can migrate. Unfortunately this is not universally appreciated in the industry.

The author indicates that drainage in a belted cable is less severe than in a shielded cable and refers to the improvement in the latter by substitution of paper for metal binder tapes. In our carbon-black (resilient binder) construction, this advantage is obtained without sacrifice to shield-to-ground continuity required for safe operation.

In Appendix I of the paper, the author refers to the satisfactory use of a viscous compound for filling terminals, consisting of a blend of cable oil and polyisobutylene (Vistanex). However, the viscosity is reported to be only 397 seconds Saybolt at 212 degrees Fahrenheit. In view of this low value, we would be interested to know the molecular weight of the polyisobutylene used in the blend.

L. F. Hickernell (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): While presenting no universal panacea, this paper is valuable in focusing attention on the troublesome problem of terminal risers and attempting to reconcile some conflicting reports which have arisen from various interpretations of so-called operating experience.

Certain statements in the paper prompt the following observations:

For 15-kv cable, the following critical heights are calculated from equation 1: 3-conductor, 750,000 circular mils, compact sector = 15 feet; and, 1-conductor, 4/0 American wire gauge, compact round = 70 feet. Practical experience would indicate that the former is very conservative, while the latter is excessive with modern standard insulation thicknesses.

Our creep data on tubes show that arsenic-lead (*F-3*) alloy can be operated as safely at 250 pounds per square inch as copper-lead at 150 pounds per square inch. It is possible that even this value may be increased in the future by further refinements in the improved extrusion methods recently introduced.

When fluid materials are used in potheads, care should be exercised to select oil (or blends) which are compatible dielectrically with the cable impregnant.

Literally speaking, the statement that "a stringy adhesive cable impregnant . . . requires a special cable which does not have the best electrical characteristics . . .," is true. Cables impregnated with our blend of mineral oil and Vistanex have very slightly higher losses than those impregnated with unblended mineral oil. However, the difference is insignificant and losses of both cables are considerably below the maximum permitted by the Association of Edison Illuminating Companies specifications. Also, the difference in cable price is negligible.

In Appendix VII under the section on Description of Cable, the author should have included "Grade of lead" or "Type of alloy" since the creep rate under pressure varies with the sheathing material.

Until further information is available, we have been suggesting the following construction:

CONDUCTOR

Compact strand—to reduce volume of oil to a minimum.

INSULATION

Type CB, shielded—to retard deterioration of oil and reduce maximum stress.

Above-standard thickness, if feasible to use special cable—to further reduce stresses on drained paper should migration occur.

BINDER

Carbon-black paper—to obtain most of the mechanical benefits, if any, of belted cable and all the superior electrical performance of shielded cable.

SHEATH

Arsenic-lead (F-3) alloy—to increase bursting strength and reduce creep under internal pressure; thereby reducing volume of channel between core and sheath in which oil can migrate.

For those who desire a *viscous impregnant*, we furnish a blend of mineral oil and Vistanex.

Wayne A. Parker (Oklahoma Gas and Electric Company, Oklahoma City, Okla.): We have not had trouble on our risers due to migration, however we have very few risers above 30 feet, the highest being approximately 50 feet. Our only trouble with these higher risers is the pressure at the top of the riser. This pressure has been so great that it has pulled the heads of the pothead body bolts through the insulator spacers. We use "Ozite B" compound in the pothead and also have some difficulty of it forcing its way out of the cap-nut gasket. The load cycle is very severe. Ambient temperature varies from 110 degrees Fahrenheit in the daytime to 70 degrees Fahrenheit at night with a load cycle of 50 amperes to 300 amperes. The cable is on a 13.8-kv circuit and rated 15 kv, 500,000 circular mils, one conductor, paper insulated, lead covered. The distance from the base of the pole to the first splice is 105 feet. The conductor is uncrushed. Insulation thickness is 0.195 inch unshielded with 0.095 inch of lead sheath and no reinforcement. It is supported at the top of the riser with a flexible copper braid wrapped around the three conductors so as to give a gripping distance of approximately 10 inches along the sheath. The type of pothead is a 23-kv G&W single conductor pothead with the mounting bracket insulated from the cable sheath. We have been able to maintain gas tightness except when the pressure has been enough to open a part of the pothead as mentioned previously.

We use only single-conductor potheads and single-conductor cable. Where it is necessary to trifucate we go to the first manhole away from the riser. We are eliminating all multiconductor potheads as rapidly as possible. Our operating experience with multiconductor potheads has been very poor. This is due mostly to the inability to obtain enough pressure on the gaskets. We feel that even on the single-conductor potheads now on the market a need for more unit pressure on the gaskets is necessary.

We have several oil-filled potheads with the reservoir under approximately ten pounds nitrogen pressure. These are only used on important circuits, such as generator leads but our operating experience with this type has been 100 per cent perfect.

Robert J. Wiseman (The Okonite Company, Passaic, N. J.): This paper should be read by everyone interested in cable risers as it explains very nicely the conditions under which cable risers operate. Cable manufacturers are asked frequently why risers do not operate as well as cable operating in a horizontal position. When the migration of the oil is referred to, then we are asked to furnish a nonmigrating compound, yet we know that none exists unless it is almost solid such as a petrolatum and the cable is below 50 degrees centigrade. Even here there will be a slow migration.

The author's suggestions for meeting the problem are possible solutions but one must not expect them to be 100 per cent proof as every case has peculiarities that can offset what is desired. A positively sealed pothead is one of the best ways of meeting the situation. It at least will delay migration and at the same time prevent entrance of moisture which is one of the major causes of terminal trouble.

Wm. A. Del Mar: Dr. Greenfield is undoubtedly correct in his view that our analogy of a sheath to a rubber pipe is not an exact one. However, in citing the forces acting on a lead sheath, external atmospheric pressure is one of them, and is certain; whereas elastic forces in lead, especially when long periods are involved, are very questionable.

Moreover, Dr. Greenfield's cylinder does not adequately represent an actual cable, especially after it has been reeled, unreeled, and pulled into a duct. Such a cable is far from having the outline of a perfect cylinder, and experience shows that it is slowly susceptible to external pressure without "crumbling."

Dr. Greenfield confirms the statement that a stringy adhesive impregnant has merit for delaying migration, but apparently gives it more merit than our Committee was willing to concede. He says that its efficacy "must be related to the temperature." In plain language, it doesn't work so well when the cable gets hot.

Both Mr. Hickernell and Dr. Greenfield claim merit for a carbon-black paper binder because it gives shield-to-ground continuity. Such continuity is not necessary, as shown by the fine operating record of the Commonwealth Edison 13,200-volt cables with a binder consisting of four insulating papers, the shields being grounded to the sheath at the joints.

Fear might be expressed that, with this arrangement, a cable failure might result in burning the shielding tapes between the point of failure and the joints and thus making the remainder of the cable unavailable for use on shorter runs or with a duct splice.

The facts are that with or without the

insulating paper between shield and sheath, the two paths are in parallel and the current in the shield will be the same in either case as it depends only on the shield impedance and the voltage, both of which are the same in the two cases.

The charging current in the shields is, of course, quite negligible. For example, the charging current of each phase of a 3-conductor 350,000 circular mil 34.5-kv shielded cable, 500 feet long, with shields grounded at both ends, would be less than 0.2 ampere at each end, and the voltage drop of the order of 1 volt.

However, if such continuity is desired, it is better attainable with metallized paper tapes, better because where there is any sheath swelling, as there is likely to be at the base of risers, the contact between binder tape and sheath becomes imperfect and much better continuity is obtainable with the low resistance film of aluminum on metallized paper than with a material like carbon-black paper, which is only semi-conducting.

With regard to Mr. Hickernell's suggested construction, compact stranding probably has some advantage. Above-standard thickness of insulation is also advantageous for the higher voltages. Carbon-black paper as a binder has been discussed above. Arsenic-lead is helpful, as indicated in the paper, although the Committee prefers to design on the basis of a hoop stress of 175 pounds per square inch rather than the 250 pounds per square inch suggested by Mr. Hickernell, at least until more experience is available. One reason for this is the relative inferiority of arsenic-lead at press-stops and in the vicinity of joint wipes.

Wayne Parker works on the safe side in trifurcating at the manhole, and his observation that multiconductor potheads are unreliable because they are difficult to seal, is an important contribution.

His difficulty is pressure at the top of the riser. The view expressed in the paper is that this occurs when the cable is hotter below than above, and therefore there is a tendency for the compound to be pushed upward toward the cooler portion. This may be because the three cables are huddled together in a steel pipe below and open to the breezes above.

Automatic Control of Metal-Clad Switchgear Serving Oil Refinery Motors During Power System Disturbances

IN a previous paper[1] by one of the co-authors, a picture of a procedure followed in planning and carrying out electrification of power drives in a petroleum refinery was presented. This paper pointed out that the use of large scale electric power in petroleum refining is relatively new. This is primarily the result of process developments requiring more mechanical energy and the industry's gradual change of viewpoint with regard to reliability of electric power versus that of steam. It is the purpose of this paper to describe some of the controls incorporated in the metal-clad switch-gear serving the Sohio Refinery at Lima, Ohio. These controls afford reliable service to this refinery during power disturbances from a system subject to lightning flashovers and similar upsets.

Refinery Use of Electric Power

The oil refiner's use of electric drive for blowers, pumps, fans, and compressors is increasing rapidly owing to several basic causes. First it is possible to generate his steam requirements at high pressure and to top the process steam through noncondensing turbine generators, thereby producing electric energy with about 4,500 Btu per kilowatt-hour. Second, it is possible to purchase electric energy for around 6 to 10 mils per kilowatt-hour in many refinery locations. Table I shows approximate comparative costs per brake-horsepower of 9 mil electric power drive with other types of drives. Electric power drive compares very favorably when the factors of labor, maintenance, supervision, and return on investment, not included in the table, are considered. Rapid process developments utilizing new drives, continuously present opportunities to improve efficiency in the use of energy.

Also in many locations, it is necessary to minimize the use of water, either because it is not available in large quantities and of suitable analysis, or because the problem of disposing of waste water thoroughly separated from oil and other contaminants is costly. This was the case at the Lima refinery. By maximum use of electric energy, the plant capacity was increased from 20,000 to 40,000 barrels per day of crude run, and a solvent lubricating oil plant was installed. Induced draft cooling towers having a total capacity of 40,500 gallons per minute were installed, and the complete expansion is being operated without materially increasing either the quantity of water taken from the ground or the capacity of the boiler house.

Reliability Required

Electrical service for petroleum plants must be dependable. It must compare with refinery steam plants where one failure in approximately 20 years is the normal case. A 4-minute outage on a delayed coking unit at a Toledo refinery means a 3-day shutdown, and a 10-minute outage at the Lima refinery would cost about $30,000.[1] Of first importance therefore, is the primary source of power. It should be chosen with a sufficient number of firm feeders to give the degree of reliability desired. Reliability, however, does not necessarily mean absolute continuity of station power. For example loss of power up to four seconds at the Lima refinery is not serious because of the complete controls incorporated in the switchgear. Here reliability becomes a function of the probability of a sustained total outage to the refinery.

Reliable electric service for the Lima refinery is derived from a duplex design all the way from 132-kv source down to 480 volts at the motors. Duplex stations were chosen over a low-voltage network because of the large distances between load centers over a 200-acre area. The duplex substation of Figure 1 is supplied from two firm feeders of a 34-kv network which is served from two separate 132-kv substations. The two 3,000-horsepower synchronous motors which drive the blowers for the catalytic cracking unit, are the largest in the refinery and are served from separate busses of the dual 4.16-kv switchgear unit. All other important motor loads are served from dual low-voltage switchgear. Originally in 1949 only the two 5,000-kva transformers shown in the center of Figure 1 were installed. The third 5,000-kva transformer was added about a year later

Table I. Approximate Utilities Costs Per Brake Horsepower Hour*

	Costs
Gas engine (30¢ gas)	0.46
Electric motor (9 mils/kwhr)	.80
Diesel engine (14¢ gal.)	.87
Gasoline engine (18¢ gal.)	2.08
Steam turbine—condensing (over 200 hp)	.88
Steam turbine—mechanical drive	2.75
Steam pump—reciprocating (small)	8.25
Steam valued @ 55¢/1,000 pounds	

*No labor, maintenance, supervision, or return on investment included.

Paper 50-261, recommended by the AIEE Switchgear Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 26, 1950; made available for printing August 28, 1950.

Figure 1. One-line diagram of refinery circuits

Figure 2. Front view, 4.16-kv metal clad switchgear showing control and protective relays

to serve the lube plant expansion. Distribution from the 4.16-kv and 480-volt switchgear busses to the catalytic cracking unit is underground. Overhead 4.16-kv radial circuits connect to the duplex low-voltage substations serving the three solvent lube units, the lube oil tankage and shipping areas, the crude distillation unit, the main tank field, and gas plant areas. The 150-megavolt-ampere 4.16-kv switchgear, houses all of the service control and protective relays for the feeders and motors served by its air circuit breakers. It also houses the field contactor and associated controls of two 3,000-horsepower synchronous motors, see Figure 2.

The feeder circuit breakers have induction inverse-time and instantaneous overcurrent protective relays. The circuit breakers of the more important circuits have single-shot reclosing relays for automatic restoration of feeder service.

The protection afforded each of the large blower motors is complete. It consists of ratio differential relays for sensitive detection of winding faults, inverse-time overcurrent relays for overload protection, instantaneous overcurrent relays for heavy short circuit protection, undervoltage relays for sustained undervoltage protection, thermal relays for protection against overheating, a damper winding relay located in the field discharge circuit for damper winding protection under near-locked rotor conditions, air-flow controls on the blower to limit motor output current to 110 per cent of rating, and a sequence timing relay for limiting the duration of the starting cycle.

Service Problems and Controls for Their Solution

Like most medium voltage lines the 34-kv network lines of the power company are overhead and are subjected to flashovers by lightning and other causes. Likewise, the refinery overhead circuits, served from the 4.16-kv switchgear, are subjected to the same types of faults. Such faults create voltage disturbances on the refinery for the duration of the fault clearing times. One of the 34-kv incoming lines is equipped with pilot wire protection and the other incoming circuit together with other lines of the network are protected by the conventional induction disk time delay and instantaneous overcurrent relays. Over-all clearing times range from under 0.2 second to approximately 1.5 seconds, most of them, however, being under 1 second.

All important induction motors are equipped with time delay undervoltage protection to ride over these disturbances.

In order to hold down the initial costs of the electric power supply, very little reserve in transformer capacity above immediate load requirements was installed. Following momentary power interruptions or severe voltage disturbances, it was found necessary to break up the reapplication of load, because the heavy inrush currents cause excessive voltage drops through these transformers. The means of segregating these loads and restoring them constituted the major control problem at Lima and is explained in subsequent paragraphs.

The 3,000-horsepower synchronous blower motors were selected for across-the-line starting and with a limited inrush of 9,330 kva. The limiting pull-in torque is 40 per cent of rating. It is, therefore, necessary to tie in the air-load control of the blowers with the electrical control of their synchronous motors in order to synchronize or pull them into step. This is done by interlocking the circuit breaker closing (motor starting) circuit with the closed position of the blower dampers so that the motors are started with the blowers unloaded. The starting circuit of each motor is interlocked with the starting sequence-timing relay of the alternate motor so that the two motors cannot be placed in the starting cycle simultaneously. Other interlocks in the closing circuit of each circuit breaker are: a phase-sequence voltage relay, a frequency relay, and an exciter voltage relay to insure alternating voltage of the proper sequence, magnitude, and frequency and good exciter voltage prior to starting. One additional interlock of a tripping relay prevents starting following tripouts by certain protective relays such as the differential relays. Upon completion of the motor starting cycles electrical interlocks cause the respective blower dampers to open and apply air load to the blowers.

Application of field to these motors for synchronizing is accomplished by a syn-

chronizing relay in the motor field discharge circuit which operates the field contactor on a slip-frequency of about 1 cycle per second and at a time when the poles of the motor are in a favorable relationship for synchronizing.

The most difficult control problems result from momentary outages to the refinery rather than from system voltage disturbances. The controls for the two conditions are slightly different and are described in the following paragraphs.

Momentary Outages to Refinery

Ordinarily, service restoration following a complete station outage can be accomplished in well under 1 second by immediate reclosure of a circuit breaker or circuit breakers. This cannot be done here because even a reclosure within 15 cycles may find the 3,000-horsepower synchronous blower motors 180 degrees out of phase with the incoming source. Such an occurrence might possibly cause mechanical damage to these motors which are coupled to high inertia gear boxes of 1,200 rpm to 5,087 rpm to drive the high speed blowers. An alternative would be to remove the motor fields prior to reclosure, but this would incur time—long enough to permit deceleration of plant motors to the extent that high inrush currents and resulting high-voltage drops would occur.

Since the 4.16-kv bus voltage under these conditions of re-energization would be less than 80 per cent normal, it becomes necessary to break-up restoration of service to the refinery. The decision, therefore, was to trip both blower motors so that upon re-energization of the station, sufficient bus voltage would be present for reaccelerating the induction motors. Re-energization of the station is accomplished through automatic reclosure of the power company's 34-kv line circuit breakers. Since it is imperative that at least one of these blowers be replaced in service within approximately 1 minute, to prevent slowdown of process, the master circuit breaker of the number 6 motor is provided with a single shot automatic recloser. This automatic reclosure is subject to the closing circuit conditions of voltage, frequency, and so forth, as previously stated. The number 10 blower motor is restarted manually from the blower room following automatic restoration of the number 6 motor.

Much thought and time were spent in choosing the means of removing the two synchronous motors during power interruptions. Power factor and watt relays though capable of detecting loss of power would be subject to false operation during certain load and fault conditions encountered. Bus voltage cannot be used because of the effect of the synchronous motors on maintaining the voltage. Interlocks with the 34-kv line relays or circuit breakers could not be used because of the possibility of the power interruption being remote from the substation. Computations of speed reduction of the refinery system on separation indicated that an under-frequency relay could be used. With a setting of approximately 58¾ cycles per second, which is considered below the minimum frequency to which the power system would ever be expected to drop, the blowers even at light load can be tripped off the line in less than 1.5 seconds.

Figure 3 shows the variation of both frequency and voltage for a staged interruption test. Note here that both motors were tripped within 1 second. The decay in motor frequency compared with that of the reference voltage, approximately 29 cycles in 0.5 second, 57 cycles in 1 second, and 83 cycles in 1.5 seconds from instant of outage, and the effect of the synchronous motors on maintaining station voltage, approximately 80 per cent of normal at instant of first motor tripping. Service was restored to the refinery by automatic closure of the power company's 34-kv circuit breaker in 157 cycles.

Time co-ordination of the control operations is as follows. With time as the only discriminating means between removal of the synchronous motors and circuit breaker reclosure to re-energize the station following power interruptions, the 34-kv line circuit breakers were set to reclose in 2.5 seconds. Although Figure 3 shows approximately 1 second was required for the frequency relays to remove the motors from service, this interval may increase to about 1.5 seconds for station loading lighter than that during the staged test. Thus about 1 second of the outage interval remains as safety margin in which to remove the motors. With 1.5 seconds as a maximum fault clearing time and 2.5 seconds as the outage interval, it was necessary to set the time-delay-undervoltage release units up to 4 seconds. Although this may seem to give a rather small margin of safety, the effect of the synchronous motors on maintaining bus voltage gives a large margin of safety in holding in the release coils.

Out-of-Step Conditions Caused by Voltage Disturbances

To take care of out-of-step conditions of these synchronous motors which may occur during system voltage disturbances, pull-out relays are installed in series with the field circuit of each motor. The relays respond to the alternating voltage induced into the field circuit when the machines slip a pole. The pull out relay of number 6 motor is connected to trip its masters circuit breaker while that of number 10 is connected to remove its

Figure 3. Oscillogram of a staged interruption test on refinery showing decay of voltage and frequency and tripping times of the 3,000-horsepower motor circuit breakers by under-frequency relays

motor field and thus place this motor in its starting cycle to be re-accelerated and resynchronized. If the duration of the voltage disturbance is not excessive following the out-of-step condition, the number 10 motor will continue in its starting cycle and resynchronize when the blower dampers automatically close to unload the motors below pull-in requirements, otherwise the starting-sequence-timing relay, set for 30 seconds, will shut the machine down. The pull-out relays of both motors are not connected for resynchronizing because of the possibility of placing both in starting cycle simultaneously, a condition which would result in less than 80 per cent bus voltage. Upon restoration of normal voltage and frequency following the completion of the starting cycle of number 10 motor, the reclosing relay of the number 6 circuit breaker will restart the number 6 motor and place it on the line.

Operating Experiences

Since the new substation and switchgear have been in service, October 1949 to July 1950, there have been 12 voltage disturbances from the power company system which caused the synchronous blower motor to drop out of step. The blower motors resynchronized successfully on ten of these disturbances. One of the failures to synchronize can be attributed to placement of the two motors in their starting cycle together following a very severe voltage disturbance. Because of low bus voltage, insufficient torque was developed to permit the motors pulling back into step. This has since been remedied by interlocking their starting cycles as described previously. The other failure was due to the oil pump motor for the blower hydraulic air control system dropping off on undervoltage. This, likewise, has since been remedied by blocking its starting circuit pushbutton in the closed position.

On July 19, 1950, Lima was struck by a tornado which severely damaged the power company's lines. It was the most devastating thing that had ever happened to their lines in that area. One 34-kv feeder remained firm, but multiple voltage dips were experienced. Both blower motors pulled out of step. One dropped into its starting cycle and resynchronized and was followed by the second upon closure of its master circuit breaker. Then on a subsequent voltage disturbance the motors again pulled out of step. One resynchronized as before but the circuit breaker of the second motor locked out because the second disturbance occurred before the reclosing relay had reset. The one motor maintained the refining process in operation.

There have been no complete power outages to the refinery from the power company system over this period from October 1949 to July 1950. A total of five fault clearing operations have occurred on the 4.16-kv feeders during that period. These were cleared sufficiently fast as not to effect the stability of the synchronous motors.

While several difficulties have been experienced and since corrected, it is felt that all major electrical problems have been overcome and it is now possible to keep important equipment on the line during any power system disturbance where complete extended interruptions are not involved.

The installation of counters on circuit breakers and field contactors, annunciator drops on important relays without built-in targets and, of course, relay targets have proved their value in analyzing the operating experiences of this automatic equipment.

Conclusions

1. The use of electric drive in refinery service is increasing rapidly for economy and other reasons.

2. At Lima, electric drive is especially valuable in that it permitted a much larger expansion of the refinery than otherwise would have been practicable with the known quantity of water available.

3. Electric power to refineries must be and can be reliable.

4. With proper controls incorporated in switchgear, reliability becomes not a function of absolute service continuity, but a function of service without sustained station outages. Controls can be provided which will permit refinery motors to ride over power system voltage-disturbances, or be quickly restored to service following momentary station outages in a manner not causing interruption to the refinery processes.

5. Operating experience with such controls at the Lima refinery is showing that the very high degree of service required for petroleum refining can be obtained by electric equipment with power supplied from a power company.

Discussion

H. M. Stewart (Humble Oil and Refining Company, Baytown, Tex.): The authors are to be complimented on this very interesting and timely presentation. The statistics given on operating experience give rather convincing evidence of the effectiveness of this control application, and add materially to the value of the paper. The excellent results attest to the effectiveness of the installation.

It is evident that the problem faced at the outset was of sufficient magnitude and importance to warrant a sizable expenditure of study, effort, and money, in view of the large debits to be expected in case of interruptions to process plant operations. The application is considered to represent a significant step toward keeping pace electrically with the strides being made by modern industrial production and manufacturing processes. Developments in the near future are likely to call for a degree of ingenuity of the order that has been demonstrated in this instance.

The design and functional aspects of the several protective features have been set forth with such clearness that there are only a few questions that might be raised regarding the application as a whole and the means devised to accomplish the desired results. Processwise, it is supposed that the timely restoration of one of the 3,000-horsepower blowers is a practically certain safeguard against a plant outage, allowing ample time for the other 3,000-horsepower unit and associated 480-volt equipment to be restored to normal operation either automatically or manually, as determined by circumstances. As the 480-volt induction motor drives are equipped with time delay undervoltage devices, they would be expected successfully to ride through most disturbances of the type described. Although there might be a fairly large number of such drives in the plant, it is assumed that their process functions are such that the time required for restarting them is not a major factor in the over-all scheme of things, even after a severe disturbance requiring re-energization of the 4.16-kv busses.

It is beyond the scope of the paper to go into the matter of transformer capacity, but the question arises as to whether plant operations might not be penalized heavily in case of an extended outage of one of the 5,000-kva stepdown transformers. It would be interesting to know whether any provisions were made to take care of such a contingency.

It is noted that one of the tie circuit breakers in the 4.16-kv bus is normally open. It is probably advisable to do this to limit the duty imposed on the feeder circuit breakers. If there are other reasons, it would be interesting to know them.

It would appear the number 6 motor might be prevented from restarting by its reclosing relay if number 10 is in trouble. Must number 10 complete its starting cycle before number 6 can be reclosed? It is likely that a winding failure in number 10 motor would be cleared so quickly by differential relay action that number 6 would continue to operate without going through a restarting cycle, but if number 6 were called upon to restart under this circumstance, is there anything inherent in the scheme that would keep number 6 from restarting, without the necessity of resetting some device interlocked with its closing circuit?

It is noted that there were five fault-clearing operations on the 4.16-kv feeders during the same period from October 1949 to July 1950, when there were 12 disturbances from the power company system. Offhand, the ratio of five disturbances on the 4.16-kv feeders to the 12 on the power company system appears to be high, as it seems certain that this ratio is out of proportion to exposure, particularly since the 4.16-kv system extends over a relatively small area and some of its feeders are underground and not vulnerable to lightning. It is suggested that future data regarding the outages on the overhead and underground portions of the plant distribution system would be interesting and might point toward opportunities of improvement, if operating experience indicates an economic justification for bettering the record.

In view of its history of success up to now, the automatic control application described by the authors seems certain of having a good record in the future, and it is believed that many engineers will be interested in any supplemental statistics that may be published in the future.

L. M. Goldsmith (The Atlantic Refining Company, Philadelphia, Pa.): The paper is an excellent one, and indicates that considerable thought was given to the selection and installation of equipment to prevent or reduce to an absolute minimum of time the power outages on the 3,000-horsepower motors on the number 6 and number 10 blowers.

We are particularly interested in this installation since we have a similar installation in the Point Breeze Refinery in Philadelphia, except that our blower motors are rated 2,500 horsepower and our operators will not permit an unplanned shut down of even one minute.

We have made no attempt to automatically restart either of these motors since the period of time during which they may be shut down is so small that even a 1-shot recloser, such as is used on the author's number 6 motor will not prevent disruption of our cycle. Although we have given this matter of keeping the blowers on the line considerable thought, we have been unable to arrive at a relay protective scheme that can be justified.

However, we do have considerable protection from power failure since we have approximately 7,000 kw generating capacity at 60 cycles in this plant as well as seven separate feeders from the local power company which assures us continuity of service under practically all but the most adverse conditions.

In the detailed description of the various types of protection described in the paper, there is no mention made of that provided for the transformer banks and the transformer busses. In our opinion, it is as important to protect these pieces of equipment, particularly by differential relays, if continuity of service and equipment protection is desired.

We agree wholeheartedly with the conclusions arrived at in the paper, particularly, since we have been interested for a great number of years in the promotion of electric drive in refinery service and have advanced it and promoted it at every opportunity. The excellent results which we have received in our own refinery agree with the conclusion the author has given concerning the reliability and high grade of service to be expected from electric drives in refineries.

G. E. Brooks (Oklahoma Gas and Electric Company, Oklahoma City, Okla.): Requirements of service reliability and the hazards and expense of shutdowns to refinery loads are well known. These, together with the economic restrictions imposed by a competitive rate for electric power, present serious problems in equipment protection and control. In this particular location, where transient outages and voltage disturbances could not be avoided, the effects of such interruptions have been minimized by careful analysis and judicious application of load segregating equipment. Automatic devices are employed to keep the loading within system capability during recovery periods without jeopardizing the various plant processes. While some problems may not yield to a sequential-restoration solution such as this one, the only course for the control engineer is to take advantage of all possible "breaks" and favor the critical elements.

Several forms of service restoration and outage-sustaining equipment have been applied to large induction and synchronous motor loads served from Oklahoma Gas and Electric Company system. Most prevalent are mechanically delayed under-voltage releases for compensator-start and across-the-line start induction motors. Field removal and restoration equipment is used where single large synchronous motors drive flour mills or pump stations. In one flour mill, where wound-rotor induction motors are controlled by sequence contactors operating in the rotor circuit, power for the contactor coils is supplied from a motor-generator set. Inertia of the motor-generator holds the contactor coils energized during transient outage, with little reduction in motor speed. A delay of five seconds in service restoration causes the equipment to return to starting position for reduced power input.

On the Oklahoma Gas and Electric Company system, the most critical problems associated with service restoration and voltage disturbances to refinery loads are where plant generators operate in parallel with the system. Various schemes, employing frequency relays, power directional and overcurrent relays, have been used to effect necessary separation.

Each installation supplying critical loads calls for consideration of the special requirements and hazards involved. Discerning and fortunate is the engineer who can solve his problem by temporarily eliminating or removing the major cause of difficulty, as was done in this instance at Lima, Ohio.

J. H. Kinghorn (American Gas and Electric Service Corporation, New York, N. Y.): The picture this paper presents of a large industrial operation which has found electric drive advantageous is an old one for many industries, but a newer one for the refinery industry. It is particularly gratifying to us in the electric utility business to note that purchased power in this case meets the requirements of economy and reliability.

Absolute assurance of power supply from any source, either purchased or locally generated is, of course, impossible to obtain. The requirement here is to obtain an overhead transmission system which although subject to lightning and other natural hazards will equal or exceed the reliability of a local generating system.

Lima is supplied by four 132-kv transmission lines, two of which interconnect with the Indiana and Michigan Electric Company system at Fort Wayne. The remaining two connect to The Ohio Power Company main transmission network. The voltage is stepped down to 33 kv for distribution in the local area. The principal substation, where all four 132-kv lines terminate, has duplicate 25,000-kva transformer banks and duplicate 132-kv and 33-kv busses. A 33-kv network is fed from this station and in addition, a single 132-kv line feeds the Sterling Substation where there is a 25,000-kva transformer bank stepping down to 33 kv and also connecting into the 33-kv network. Lima Refinery is supplied by two 33-kv lines. One is 2.13 miles long and comes directly from the Sterling Substation. The other is 0.17-mile long and comes from a sectionalizing station in the main 33-kv network. The fact that both lines are quite short and of good construction makes it unlikely that both will be out of service simultaneously. The shorter line is protected with pilot wire relays which will clear short circuits in 0.15 second including circuit breaker time. The longer line has instantaneous and induction overcurrent relays which will clear short circuits in from 0.15 to 1.4 seconds depending on their location. Ninety per cent of the line length is covered by the 0.15-second clearing time. With this short time, it is unlikely that temporary flashovers will cause enough damage to prevent successfully re-energizing the line immediately after a tripout. There have been no tripouts on these lines between January 1 and September 1, 1950. The tornado referred to in the paper damaged the other 33-kv lines supplying the network but left Sterling Substation feeding the refinery and the remaining sound portion of the network.

The requirement that after a power interruption the incoming circuit be reclosed after the synchronous blower motors have been removed but before the time delay undervoltage devices have shut down the various induction motors is a severe one and leaves little leeway for inaccuracy in the devices employed. For instance, if the pilot wire protected circuit were open and a severe short circuit should occur on the line from Sterling, the voltage at the refinery would immediately dip and the

undervoltage devices start timing. Under the worst condition, the circuit breaker at Sterling would open in 1.4 seconds. It would reclose about 2.5 seconds later or only 0.1 second before the undervoltage releases operate. Under the best condition, the circuit breaker at Sterling would trip by instantaneous relays and the reclosure would occur 1.35 seconds before the undervoltage releases operate approximately as shown in Figure 3 of the paper.

The margin of safety for the worst condition might be increased by reclosing more quickly but this would reduce the time between synchronous motor opening and power restoration. Because of the uncertainties of the tripping time of the underfrequency relays, this does not seem advisable. It is to be expected that this occurrence will be quite rare. It is evident that to insure correct action on those occasions, periodic checks will have to be made on the timing of undervoltage releases and circuit breaker reclosing timers to make sure they remain in proper operating condition.

P. O. Bobo: Mr. Stewart is correct in that the restoration of one 3,000 horsepower synchronous blower motor to service following a momentary station outage is sufficient, providing also that the important induction motor loads are maintained on the line. These motors, as Mr. Stewart says, are expected to ride over disturbances of this type. He also is correct in his assumption that the reacceleration time of the motors after such disturbances is not a major factor in the over-all scheme of things, but the element of time does require automatic equipment to prevent loss of processes; the time required for manual restoration of the many individual drives would be excessive and result in serious loss of production. The time-sequence in restoring electric drives at Lima largely determined the amount of automatic equipment required. Of course, all drives cannot be simultaneously restored because of the limited transformer capacity. Fortunately the two 3,000-horsepower motors can be dumped, if one is subsequently restored to service within one minute. This permits the use of the simple time-delay undervoltage release to as much induction load as transformer capacity can safely restart and a minimum of automatic controls to restart the dumped load upon subsequent voltage recovery.

Only one bus-tie circuit breaker is normally closed in order to limit the duty imposed on feeder circuit breakers.

The starting of the two 3,000-horsepower motors are electrically interlocked so that they can not be started together, either manually or automatically. However, the controls of the two motors function differently for operations resulting from momentary power interruptions to the station, than they do for those resulting from out-of-step conditions. For power interruptions, both are tripped by their underfrequency relays. One is restarted by automatic circuit breaker reclosure upon restoration of good voltage and frequency and the other is left off to be manually restarted.

For the out-of-step conditions, the two motors are interlocked so that if both pullout together, they will not both restart together and cause a low-voltage condition. One motor is placed in its starting cycle by removal of its field while the other motor is tripped—to be restarted automatically upon completion of the starting cycle of the first.

The high ratio of feeder faults to power company line faults as noted by Mr. Stewart is due to man-made faults within the refinery during a construction period. The ratio undoubtedly will drop in the future.

To answer the inquiries of Mr. Stewart and Mr. Goldsmith, the three 5,000-kva transformers are individually protected by ratio differential and overcurrent relays. In the event of an emergency loss of one transformer, the refinery load can be carried for extended periods on any two of the three transformers. Figure 1 of the paper shows how connections can be made through bus-tie circuit breakers.

It is interesting to note that the degree of reliability desired for the plant referred to by Mr. Goldsmith requires seven incoming feeders from the local power company plus generation of their own. Mr. Brooks pretty well sums up problems of this type in his statement "While some problems may not yield to a sequential-restoration solution, the only course for the control engineer is to take advantage of all possible breaks and favor the critical elements." At first sight at Lima, there appeared to be no "breaks," but when faced with the facts, and the costly results of a shutdown or preventative alternatives, round table discussions with process men and electrical men of the refinery company, with the power company engineers, the contractor and equipment supplier, it was found that certain equipments could be disturbed for short periods without serious loss of process. The result was the subject control system, which to date has proved its reliability.

Mr. Kinghorn's picture of the 132-kv and 34-kv lines to Lima, and his analysis of the close timing requirements show what can be accomplished by automatic controls on a system subject to several transient interruptions, but to date no extended outages.

In conclusion, two general statements are here given:

First, many cases of either severe damage or loss of production can be prevented by utilizing equipment automatized to perform certain functions in which the "what-to-do thinking" has been done beforehand instead of afterwards. Second, the probability of permanent faults to feeders serving important loads—either main lines serving a station or feeders therefrom—can be greatly reduced by high speed clearing of faults such as by pilot wire, carrier-current, or distance relays.

The authors wish to thank these gentlemen for the important contributions they have made to this subject.

An Electric Analogue Computer Using the Photo Cell as a Nonlinear Element

ELDO C. KOENIG
ASSOCIATE AIEE

THE electric analogue computer was built primarily for the purpose of analyzing magnetic circuits; however, its application can be extended to cover the solutions of many other nonlinear systems in the fields of fluid flow, aerodynamics, and mechanics. During the past 12 months of operation, the computer has been used extensively to analyze the magnetic circuit of salient pole and cylindrical rotor synchronous machines for the purpose of investigating iron losses, effect of saturation of the component parts on the characteristic saturation curves, and for determining the normal field excitation. Not only is the amount of labor greatly reduced in solving magnetic saturation problems with the computer but more accurate solutions are obtained. Without a computer it is often necessary to arrive at solutions by empirical methods which sometimes give erroneous and unreliable results.

The photo cell was used in the basic element because its features make the computer relatively simple in design and operation. The current through an element, of which the photo cell is a component part, is a single valued function of the voltage across the element. The computer then is a direct electric analogue of the system being analyzed, and the effects of changing the value of a component of the system can be observed readily by making the corresponding change on the analogue. The purpose of this paper is to describe the electric analogue computer as a device for solving problems involving single valued nonlinear parameters and to describe in general its design features.

Paper 50-263, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted March 15, 1950; made available for printing September 12, 1950.

ELDO C. KOENIG is with Allis-Chalmers Manufacturing Company, Milwaukee, Wis.

The author is indebted to Dr. Sterling Beckwith for suggestions in the preparation of this paper, and for his valuable aid in the development of the analogue computer and in applying its use to the analysis of magnetic circuits; to Walther Richter for his suggestions in the design and building of the computer; and to John Borsk and staff for the splendid co-operation and assistance in carrying out the laboratory work. All are of the Allis-Chalmers Manufacturing Company.

Photo Cell Characteristics and Features

The vacuum photo cell has unique advantages for use as a nonlinear parameter. Representative characteristic curves of a silver-cesium oxide-cesium cell are shown in Figure 1 as curves A, B, and C. The light intensity was the parameter for obtaining the three curves. The important feature here is that when the light excitation is changed from one value to another, the per-cent change in current is essentially the same at all voltages. Therefore, a family of curves is obtainable by varying the amount of excitation.

These curves in the upper region have essentially a constant slope. This suggests the photo cell to have the characteristics of an inherent constant and a variable resistance in parallel. Curves A_1, B_1, and C_1 of Figure 1, which are the characteristic curves of a constant resistance, are drawn through the origin with slopes equal to the constant slopes of curves A, B, and C, respectively. When the ordinates of each of the curves A_1, B_1, and C_1 are subtracted from the corresponding ordinates of each of the respective curves A, B, and C, the curves A_2, B_2, and C_2 result. Each of these resultant curves is the characteristic curve of the inherent variable resistance for a particular excitation value. When setting up the analogue of a magnetic circuit, the inherent variable resistance of the photo cell is made to represent the inherent variable reluctance of the magnetic material of that circuit.

If a group of cells is excited from a single light source and the cells for a given light intensity are adjusted to give equal current outputs for a given voltage, then for an increase of light excitation, the current output of each of the cells will increase an equal amount. Therefore, cells to represent equal nonlinear parameters can be conveniently excited from the same source of light and their current outputs varied a like amount, simultaneously, by changing the light output of the exciting lamp.

Since the light excitation circuit and the photo cell circuits are completely isolated from each other, there is no problem of circulating currents through metallic connections between circuits. This feature is not possible with other electronic tubes requiring bias.

After the photo cells of the silver-cesium oxide-cesium type have been properly aged (see Appendix I for aging method), the characteristic curves of the majority of the cells show close agreement. Approximately 70 per cent of the cells of this type used in the computer were selected as having current-voltage characteristics near enough alike to give the desired accuracy. In Figure 2, curves U and L and curves U' and L' are the limits within which the characteristics of the inherent variable resistance and constant resistance of the cells had to be contained for maximum allowable error. Curves A and A' are the average characteristics of 60 cells which fell within the limits.

The Basic Elements

One or more photo cells in combination with one or more constant resistances in series or parallel, and in some instances voltages within the element network, form

Figure 1 (left). Characteristics of a single photo cell showing family of curves possible by varying the amount of light excitation

Figure 2 (right). Limits of the photo cell characteristics for selecting cells

several basic elements which may be used to represent the nonlinear parameters of systems.

Figure 3(A) shows the characteristic current-voltage curve for a basic element number 1 consisting of a constant resistance in series with the photo cell. The characteristic curve of the photo cell now approaches the characteristic curve of the series resistance instead of the current axis as the voltage approaches zero.

A second basic element consists of an aiding or an opposing voltage in series with the photo cell in order to shift the characteristic curve of the cell to the left or to the right with respect to the current axis as is shown in Figure 3(B). Since the cell current is very small, around ten microamperes, the voltage drop through the voltage sources used in the circuit will be relatively small. Therefore, the amount of shift will be essentially equal for all values of current flowing through the circuit.

Figure 3(C) shows a third basic element which consists of a photo cell and an auxiliary circuit for inverting the characteristic curve of the cell. The plotted current I is equal to the current I_S through the auxiliary circuit minus the current I_C through the cell.

A fourth basic element is shown in Figure 3(D). The effect of the resistance in parallel with the cell is an increase in the total current through the basic element which results in an increase in the slope of the characteristic current-voltage curve.

In addition to the examples just given using the photo cell and only one other component in the basic element, the cell and any combination of two or more components may be used. Still another parameter, the light excitation, can be changed to produce the effect described in the previous section. Also, instead of one photo cell in its branch circuit, two or more may be used to increase the current capacity, which is controlled by the cell rating.

With a single fixed relationship between the analogue and the represented system, it may not be possible to represent the nonlinear parameter for an infinite number of values of the function. However, when such is the case, results of sufficient accuracy may be obtained by matching the characteristics only over the range of values expected to be involved in the solution for that given set of conditions.

Representation of the Inherent Variable Resistance Characteristic of the Photo Cell by a Mathematical Expression

To determine what type of nonlinear parameters could best be represented by the current-voltage characteristic of the photo cell a number of equations, each representing one or more family of curves, was analyzed. The following equation describes most accurately the functional relationship between current and voltage of the cell and is of the form found by Gokhale[1] to be the law which more nearly represents the magnetization curve near saturation:

$$I = S - e^{-[a(E \pm H) + c]}$$

where

I = current through the inherent variable resistance of the photo cell
S = intrinsic saturation value of current
E = electromotive force across the cell and any opposing or aiding voltage in series
$+H$ = aiding voltage in series with the cell
$-H$ = opposing voltage in series with the cell
a,c = arbitrary constants

The current-voltage characteristic curve of the inherent variable resistance of the cell which was used for comparison with the equation was the average of those which fell within the limits shown in Figure 2 and is the curve A of that figure.

A particular equation resulted from the general equation by assigning a value of H equal to 0.015 (normalized for unity to equal 100 volts) opposing the voltage E. The constants a and c were calculated from the values at the points on curve A corresponding to E equal to 0.20 and 0.40 and found to equal 6.15 and 1.45, respectively. The resulting particular equation is:

$$I = 1 - e^{-[6.15(E - 0.015) + 1.45]}.$$

Curve A of Figure 4 shows the per-cent error in representing curve A of Figure 3 by the equation. Curves B and C of Figure 4 are the per-cent error limits for selecting the photo cells. From E equal to 0.2 to 1.0 the equation represented the average characteristic curve exactly for the points checked and did not exceed the allowable error for selecting the cell between the values for E equal to 0.13 and 1.0

Fundamentals in Setting Up the Analogue of Magnetic Circuits

To establish the relationship between flux and current, and magnetomotive force and electromotive force the characteristic curve of the inherent variable resistance of the photo cell is made to match as nearly as possible the characteristic curve of the inherent variable reluctance of one cubic inch of magnetic material. Figure 5 shows curve P', the average characteristics of the inherent variable

Figure 3(A). Basic element number 1 consisting of a resistance in series with the photo cell

resistance of the cells of Figure 2, matched as closely as possible with the curve M', the characteristics of the inherent variable reluctance of silicon steel. However, in order to match the two curves, the current axis had to be displaced to the left of the flux axis by 1.5 volts, as is shown in the figure. To consider this displacement in the analogue circuit, the basic element number 2 of Figure 3(B) can be used. The voltage V in series with the cell must aid the voltage applied across the element.

After the two characteristic curves of the inherent variable resistance and reluctance are matched, it is usually found that the value of the inherent constant resistance of the cell is too great in representing the inherent constant reluctance of the magnetic material. Consequently, curve P of Figure 5, which is the current-voltage characteristics of the cell, will be too low in matching the curve M, which is the magnetization curve of the one cubic inch of silicon steel. By the addition of an external resistance of proper value in parallel with the cell, curve

Figure 3(B). Basic element number 2 consisting of a photo cell with either an opposing or an aiding voltage in the cell circuit

M will be matched as closely as possible. The basic element number 4 of Figure 3(D) has an external resistance in parallel with the cell and can be used to make this correction.

From the foregoing discussion, when an analogue circuit is to represent a magnetic circuit, a combination of the components of the basic elements numbers 2 and 4 of Figures 3(B) and 3(D), respectively, must be used to represent accurately the magnetization curve of one cubic inch of magnetic material. The resulting new basic element would then consist of an external resistance in parallel with a photo cell and an aiding voltage of 1.5 volts in series with the cell. For simplifying purposes, the magnetization curve could be represented almost as accurately by using basic element number 4 in series with the aiding voltage of 1.5 volts, but the aiding voltage need not be a separate source in series with each of the number 4 elements used in the analogue circuit. Instead, an additional voltage equal to 1.5 volts multiplied by the number of elements in series can be added to the true voltage to be applied across that group of number 4 elements in series. This method is used on the computer for setting up analogues of magnetic circuits.

Since nonmagnetic material has linear flux–magnetomotive-force characteristics, any nonmagnetic material in series with magnetic material in a magnetic circuit can be represented by a constant resistor in the analogue. The relationship between reluctance and resistance is established from the relationship between magnetomotive force and electromotive force, and flux and current.

For conditions of magnetic and nonmagnetic material in parallel in a magnetic circuit, the flux that passes through the nonmagnetic material is represented by additional current through the external parallel resistor of the basic element. Therefore, to meet this condition in the analogue circuit, an adjustment of the parallel resistor of the basic element is all that is required.

Description of the Computer

There are 60 basic nonlinear elements and a number of electromotive forces and separate linear resistors used in the computer. A cell and an adjustable constant resistor in parallel make up the basic element which is number 4 of Figure 3(D). The elements are not permanently connected to form a particular network but can be readily connected in any fashion. The electromotive forces

Figure 3(C). Basic element number 3 consisting of photo cell and an auxiliary circuit for inverting the characteristic curve of the cell

and adjustable linear resistors are available for inserting between the basic elements wherever required. The computer is shown in Figure 6.

An example of how the basic elements, resistors, and electromotive forces can be connected on the computer to represent a magnetic circuit is shown in Figure 7. The magnetic circuit represented is that of a salient pole synchronous machine for the conditions of open circuit and zero power factor lagging or leading. It is assumed the teeth and pole head saturate and the remaining magnetic material of the circuit has infinite permeability.

Five basic elements in series represent the reluctance along each tooth. The reluctance of each pole tip is represented by three elements in series. The resistors R_S and R_G represent the reluctance across the slots and air gap, respectively. The electromotive forces, E_S, represent the magnetomotive-forces in the stator slots resulting from current flow in the stator conductors. The sum of the electromotive forces, E_G and $(1/2)E_T$, equal the voltage representing the resulting magnetomotive force acting at the

Figure 3(D). Basic element number 4 consisting of a photo cell in parallel with a resistance

Figure 4 (left). Error in representing the characteristics of inherent variable resistance of photo cells by an exponential law

Figure 6 (right). Electric analogue computer

point under consideration across the pole plus the product of the number of elements in series and 1.5 volts. For example, E_a nearest the quadrature axis plus $(1/2)E_T$ equals the true voltage plus the product of 8 and 1.5 volts. As discussed in the preceding section, the 1.5 volts is a correction factor required for the matching of the photo cell characteristics with the magnetization characteristics of one cubic inch of magnetic material. When open circuit conditions are considered, E_s and E_a are zero and the only electromotive force acting is E_T.

The photo cells of the elements of the computer are excited from six separate incandescent light sources with ten cells excited from each source. The excitation of each cell is adjusted initially by a shutter on the opening through which the light passes to the cell. The excitation of the ten cells in each group can be varied simultaneously by changing the voltage across the exciting lamp. A master control is used for changing the voltage across all the exciting lamps and thereby can be used to adjust the excitation of all 60 of the cells simultaneously.

The example circuit of Figure 7 illustrates the convenience of the system of simultaneous control of the excitation of a group of cells. Since each of the ten cells of a row represents the reluctance of magnetic material of the same cross-section, all ten of the cells in each of the five rows are excited from a single light source. Therefore, to adjust the analogue circuit for a change in tooth paper the voltage across the exciting lamp for each row of cells is changed. When the tooth area is changed with the taper held constant, an accompanying change of voltage across all five of the exciting lamps is made with the master control.

The voltages and currents in the analogue circuit are unidirectional and are not amplified. The values of current in different parts of the network system may cover a range from zero to approximately

Figure 5. Matching of magnetization characteristics of silicon steel with the characteristics of a basic element

Figure 7. Analogue block diagram of the magnetic circuit of a salient pole synchronous machine assuming only the teeth and pole head saturate

Figure 8 (left). Comparison of an open circuit saturation curve of a salient pole synchronous machine obtained from test with the curve calculated on the analogue computer

Figure 10 (upper right). Power supply of computer

125 microamperes; however, the current through individual photo cells seldom exceeds 15 microamperes.

The unidirectional electromotive forces are supplied by half-wave rectifiers. The values of electromotive forces can be varied from zero to as high as 2,000 volts in some cases. As many as ten separate and isolated voltages can be varied simultaneously. A description of the method used is given in Appendix II.

The circuit of Figure 7 employs the method of simultaneous variation of a number of isolated voltages. Each of the nine electromotive forces E_S in each of the four rows and also each of the ten electromotive forces E_G can be varied simultaneously by a single control to adjust for a change in current flowing in the stator conductors.

The network arrangement of elements shown in Figure 7 is similar to the actual network used in part for calculating the saturation curves of salient pole synchronous machines. A separate circuit is set up on the computer for calculating the pole saturation.

Possible Sources of Error

Since very small currents flow through the circuits with relatively high voltages impressed, special precautions were exercised in the construction of the instrument panels and the building of the control apparatus in order to avoid difficulties from leakage currents. The problem was alleviated to a great extent with the use of the more recent plastics. As a special precaution in guarding against future leakage currents, the computer apparatus was completely enclosed and air conditioned. With these precautions exercised there have been no leakage difficulties.

The error involved in the measurement of current and voltage of the analogue circuit is primarily that which is normal for the measuring instruments. Since the resistance of any element of the circuit is large, in the order of megohms, a microammeter with an internal resistance of approximately 100 ohms will introduce an insignificant error in addition to the normal error of the meter. Voltages of the circuit are measured by balancing a variable voltage, which can be measured with a conventional voltmeter, against the unknown voltage. Since the analogue circuit is not disturbed by this method of voltage measurement, the error introduced here is that which is within the voltmeter.

Figure 9. Current-time characteristics of photo cells

In representing the magnetic circuit of a salient pole synchronous machine by the analogue circuit shown in Figure 7, the following are likely sources of error in the solution:

1. The current-voltage characteristics of the basic element not matching exactly the flux–magnetomotive-force characteristics of the magnetic material.
2. The current-voltage characteristics not remaining constant with respect to time.
3. Too small a number of elements arbitrarily chosen to be connected in series.
4. Too small a number of series groups of elements arbitrarily chosen to be connected in parallel.
5. The assumed direction of flow of flux not the true direction, and the direction changing with increased saturation.
6. Neglecting certain parts of the magnetic circuit in setting up the analogue for simplifying purposes.

There nearly always will be some elements of the circuit of Figure 7 operating at the lower region of the current-voltage curve where this curve and the magnetization curve are not as accurately matched. Consequently, very small errors will be introduced at any point on the calculated saturation curve of the machine, but the accuracy will tend to improve as saturation increases.

The amount of fatigue or the amount the current-voltage characteristics of the cell changes with time is a function of the current flowing through the cell and also of the voltage applied. Two or more cells may be put in parallel in the basic element to decrease the amount of current flowing through any one cell and thus reduce fatigue. If high voltages in the intrinsic region are required and/or the condition of high currents through the cells exist, the error from fatigue can be held to a low value by reducing the time required for recording the data on the circuit and also by recording the highest values of voltage and current first. In calculating the

saturation curves of electric machines at the highly saturated region, a current drop of 2 per cent after ten minutes is seldom exceeded.

The number of elements in series to represent the saturation of the teeth shown in Figure 7 is typical of the number used in the saturation studies of machines. The greater the number, the more true the representation of the actual conditions, for each element represents a parallel sided section of tooth, the width being the mean width of the actual tapered tooth section.

For the circuit of Figure 7 the number of groups of series elements is equal to ten which means the equivalent machine has ten teeth per pole. If the number arbitrarily chosen is small, the principal inaccuracies resulting will be in connecting the elements representing pole head saturation in the circuit, for it may become a choice whether to connect an air gap resistance on one end of an element or the other. In the saturation studies of machines it was found that an equivalent ten teeth per pole meet the requirements for most machines.

An assumed direction of the flow of flux is required in determining the values and locations of some of the components of the analogue circuit. If the assumed direction is correct for one condition of saturation, it may be in a different direction for other conditions. The direction of the flow of flux in the pole head must be assumed in order to divide it into sections to be represented by the basic elements. The direction of flow of flux is assumed for unsaturated conditions. If the direction changes for saturated conditions, the resulting error in calculating the machine saturation curve will not be large.

In setting up the analogue circuit of an electric machine, certain parts of the actual magnetic circuit are neglected for simplifying purposes since their affects on the final results are negligible. An example is that of pole and stator end leakage.

The accuracy obtained in calculating the open circuit saturation curve on a typical machine is shown in Figure 8 by comparing the test curve A with the calculated curve B. Results of calculations of the saturation curves of rotating machines indicate an accuracy of $\pm$ 2 per cent in magnetomotive force.

Conclusion and Summary

The Electric Analogue Computer using the photo cell as a nonlinear element shows promise as a useful device for solving many types of problems involving single valued nonlinear parameters. This is deduced from the following summary of important points of the paper:

1. The photo cell as a nonlinear element has distinctive merits with respect to flexibility and simplicity.

2. The basic element consisting of the photo cell in combination with one or more resistors and electromotive forces is general in application as a nonlinear function of a dependent variable.

3. Operation of the computer has proved successful in the analyzing of magnetic circuits.

Appendix I. Method of Aging Photo Cells

It was found that most photo cells are unstable and require some light aging before they are suitable for use in the computer. When first put into operation, the cells have either a rising or falling current output characteristic with respect to time. This instability in part appears to be the result of a gas sealed within the cell as discussed in detail in reference 1. By subjecting the "gassy" cells to cyclic periods of excitation and zero excitation at the higher voltages with outputs of current of relatively high values during the excitation period, they can be made to approach stable conditions.

Curves A and B of Figure 9 show the current-time characteristics of two photo cells, numbers 1 and 2, respectively, taken when the cells were first put in operation and representing the two extreme cases of rising and falling current characteristics. Curves C and D of the same figure were taken following curves A and B after a 2-hour rest period and represent the characteristics of cells numbers 1 and 2, respectively. Curve E shows the current-time characteristics after the aging period is completed. The improvement in stability, which results from aging, is evident by the comparison of the curves.

Most cells can be stabilized after about 25 cycles; each cycle is made up of a 5-minute excitation period followed by ten minutes of zero excitation. The cells in the computer which have been aged by this method show less than 1 per cent drop in current output after a period of 20 minutes of operation when operating in the region near intrinsic saturation, and with approximately 150 per cent rated current. The cells regain the 1 per cent current output after approximately a 1-hour rest period.

The functional relationship between current and voltage of the photo cell appears to remain constant after long periods of operation. Characteristic curves have been taken after the cells have stabilized and checked again after long periods of intermittent operation. The results show that there is no apparent change.

Appendix II. Description of a Power Supply

Figure 10 shows a diagram of a power supply used in the computer. Ten separate unidirectional electromotive forces are obtained from the outputs of half-wave rectifiers supplied by ten windings on the center leg of the 3-legged core transformer. The single winding on the low-voltage side is connected to a source of a-c supply through an autotransformer, which is used to vary all of the ten unidirectional electromotive forces simultaneously.

A second group of ten separate windings on an outer leg of the transformer supplies current to the heater filaments of the rectifiers. The single winding on the low-voltage side is connected directly to the a-c source.

All windings are insulated carefully from one another to hold the current leakage to a minimum.

Information Theory Applied to System Design

W. G. TULLER
NONMEMBER AIEE

A DISCUSSION of general principles of the application of information theory to system design is followed by a specific example of its use in studying the private line air traffic control communication system.

The statistical theory of communications, developed over the past few years and often called information theory, can be of real assistance in the design of communication systems. Although very little can be obtained in system performance by the use of this theory that could not have been predicted by earlier methods, the theory provides a logical and straightforward method of evaluating a communications problem and gives a direct answer as to the effect of necessary compromises from the ideal in bandwidth, power, rate of transmission of information, and so forth. In this paper a short general discussion of the method will be followed by a practical example of a communication system that has been designed, on paper, in accordance with the method. This is the interim "private line" communication link between the airport traffic controller and the aircraft under his surveillance.

Design Principles

A preliminary statement of the method of system design is deceptively simple. One merely computes the maximum rate at which information must be transmitted in units of bits or Hartleys* per second. The available bandwidth and carrier to noise ratio are then used to determine the maximum rate at which information may be transmitted over the facilities available. If the second quantity is greater than the first, the system designer is indeed fortunate, the information may be transmitted over the transmission link, and the problem is reduced to one of inserting a controlled redundancy into the message to improve transmission clarity. If the facilities are inadequate to the task, then the designer must strive either to obtain more facilities, that is, bandwidth, power, sensitivity, or he must wring some redundancy from his message if he does not give up entirely. In either event a straightforward calculation yields an immediate answer as to the possibility of accomplishing the desired task with the available equipment and spectrum. If by any chance either transmitter power, receiver sensitivity, or transmission bandwidth are under the complete control of the system designer, then he may choose one of these to allow transmission of his information at the required rate. Usually, however, this is not the case.

The equations used to determine the information content of the set of possible messages and the information handling capacity of the system are well known[2,3] but will be repeated here for completeness.

To find the information content of the set of messages that may be transmitted, use the expression.

$$H_1' = n' \log_{10} s \tag{1}$$

Where H_1' is the rate of information output of the message source in Hartleys per second, and s is the number of possible equally likely significant values (the case where the values are not equally probable was taken up by C. E. Shannon,[1] but is of practical use only when complex coding is permissible), which the message may have at any given time, and n' is the number of times per second a value must be chosen in order not to lose information. If our message is in the form of an electrical signal, and has no redundancy, that is, its future may not be guessed with significant accuracy from a priori knowledge or from the past history of the message, we have

$$s = 1 + \frac{S}{N} \tag{2}$$

where S/N is the signal to error (noise) ratio at the input to the modulator in the generalized communication system shown in Figure 1. S/N must also be the signal to error (noise) ratio at the output of the demodulator in this system if no information is to be lost.

Said in another way, from the viewpoint of the information source, s is the number of symbols that could have been emitted at any instant of time. Of this ensemble, one will be emitted n' times per second. This relation defines n' in equation 1. In electrical terms we have

$$n' = 2f_e \tag{3}$$

where f_e is the premodulation and postdemodulation bandwidth of the system shown in Figure 1. The coder and decoder of Figure 1 may be used to remove and/or insert redundancy into the message as desired.

To determine if our facilities are adequate for the information source we use

$$H_2' = 2B \log_{10}\left(1 + \frac{C}{N}\right) \tag{4}$$

* Bit is defined as a unit of information capacity, equal to one binary decision, or the designation of one of two possible values or states of anything used to store or convey information.

Hartley is defined as a unit of information capacity, equal to one decimal decision or the designation of one of ten possible values or states of anything used to store or convey information.

Paper 50-266, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 27, 1950; made available for printing September 6, 1950.

W. G. TULLER is with Melpar Incorporated, Alexandria, Va.

Although the writer served on Special Committee 41 of the Radio Technical Committee for Aeronautics the material in this paper is primarily the work of a large group on this committee, too numerous to name individually. The evaluation was a group effort under the guidance of Vernon C. Weihe, and should be acknowledged as such. A complete report is given in RTCA Paper 116-49/DO-30.[1]

Figure 1. Generalized communications systems

Here H_2' is the information handling capacity of the transmission link, B is the bandwidth of the elements between modulator and demodulator, and C/N the carrier-to-noise ratio at the input to the demodulator.

If H_2' is greater than H_1' the system is adequate to handle the demands of the source of information. If not, as has been mentioned before, something must be done to either the information or the communication equipment.

Application of Theory to Air Traffic Control Problem

To go now to a practical example, Special Committee 41 of the Radio Technical Committee for Aeronautics had as its task an operational and technical evaluation of a "transition period air traffic control communication system," a private line between the air traffic controller and each aircraft under his control. The purpose of such a system is to provide more rapid exchange of messages between a ground station and each aircraft on an individual communication link than can be done by radio telephone. The evaluation was done by Special Committee 41 using information theory, and the techniques used in the evaluation of the ground-air link are given in the following paragraphs.

Available for this communication system is the band of audio frequencies between 5,000 and 7,000 cycles. This band lies between the voice channel and the subcarrier used in the very high frequency omnidirectional radio range (VOR) equipment. It is available on VOR, VHF (very high frequency) localizers, and VHF tower and VHF enroute communication transmitters. It also is available in the standard VHF navigation receiver. Thus, if this audio band could be used, no new radio equipment would have to be added on the aircraft or on the ground to perform the private line function. Only terminal equipment would be required. Inasmuch as the radio frequency carriers may be modulated by other subcarriers, only 15 per cent modulation is available for private line. This means the system must operate well with a minimum carrier to noise ratio.

Substituting bandwidth and minimum carrier to noise ratio in equation 4 we have

$$H_2' = (2)(2{,}000)\log(1+1) \tag{5}$$

Since C/N must be assumed a minimum of unity (actually rms carrier to noise ratio must be 8 decibels to obtain a peak carrier to noise ratio of unity) it is convenient to take H_2' in bits per second and use a logarithm to the base 2. This gives

$$H_2' = 4{,}000 \text{ bits per second} \tag{6}$$

as the capacity of the equipment. The remainder of the system design comprised an attempt to force the information source to fit this mold. By the use of visual presentation to the pilot, and automatic or key punch message selection, a predetermined group of messages may be used and one chosen and presented efficiently.

As a result of considerable work by the operational group, the messages to be presented, and their display, were chosen as shown in Figure 2. In this figure the possible messages that may appear in each position are shown in tabular form beneath the rectangle depicting the slot through which the message appears. Circles indicate buttons to be pressed by the pilot to tell the controller that he is acting on instructions (corresponding to "WILCO").

From Figure 2 it may be seen that a complete ground-to-air message comprises seven "words" and that each word has a maximum of ten possible choices or values. This sets s in equation 1 as ten. Since transmission must be in binary code to operate at minimum carrier to noise ratio, s was fixed at 16, the nearest larger power of two, or 2^4, with a resultant possibility of an increased number of messages or a safety code (one employing redundancy) should it be desired. From Figure 2 we also obtain n as seven words per unit of time in which an aircraft must be contacted.

Operationally it was determined that each of at least 15 aircraft should be contacted every 5 seconds, and that at least 60 assignable aircraft identities should be available. The aircraft identity, which makes the private line private, therefore requires two more words.

Summing up, nine words per aircraft must be transmitted in 5/15 or 1/3 second. This means a rate of 27 words per second. Each word has a content of four bits, since 16 choices are available. The information handling capacity required of the system is therefore 108 bits per second.

Comparing the required capacity of 108 bits per second with the available capacity of 4,000 bits per second, we see that ample system information handling capacity is available. Since equation 4 is based on the use of ideal filters, a conservative design would only attempt to obtain 2,000 bits per second.

Efficient Use of Excess Channel Capacity

Since the available channel capacity is so much greater than required, it was recommended that controlled redundancy be introduced in the form of a self-checking code. If a word is sent once in the marks and once in the spaces of a code group, it is immediately apparent if an error has been made. This safety coding requires a capacity of 162 bits per second. The additional capacity still available may be used to obtain improved operation at low carrier to noise ratios or to contact more aircraft per second. In practice, some capacity also must be used up in this particular system to allow for transmission lag through the link and to allow for a "screen lift" signal, not previously mentioned, that assures the pilot his instructions have been checked on the ground, after retransmission from plane to ground, and found accurate. Inasmuch as the private line is to be operated in conjunction with the phase and inter-

Figure 2. Information to be presented by cockpit display

ference sensitive VOR circuits, it was thought that the remaining additional capacity would best be used in protecting these circuits and in obtaining improved performance at low-signal levels.

Results of Analysis

The preliminary analysis given above ensured that a conservative system design could be obtained, and that the necessary equipment design would be a relatively straight-forward problem. It was then possible to proceed with confidence to a consideration of specific equipment.

The example given illustrates certain basic principles worthy of special note. These are the calculation of system information handling capacity and information source output, the use of a coding scheme exactly fitted to the limited information to be transmitted, and controlled redundancy to obtain improved system reliability.

The Further Development of Fluid Mappers

A. D. MOORE
FELLOW AIEE

Synopsis: Fluid mappers can be built to simulate, and lead to the solution of a great many field situations in electrostatics, electromagnetics, eddy currents, heat conduction, and other analogous cases. Distributed sources, as well as ordinary sources, may be represented. Fluid mapper techniques are well enough developed so that many fields now can be simulated with sufficient accuracy, by applying tested routines to building and operating the mappers. But like all other devices, fluid mappers have their own special problems, troubles, and limitations. Also, they will be called upon to go beyond the limits within which the writer's work has been carried out. Further invention, research, and development of additional techniques are called for. By pointing out the problems and limitations, the paper does two things. First, those who are building fluid mappers for teaching, research, or application, are assisted in understanding the limitations and in minimizing inherent effects tending to reduce accuracy. Second, the numerous problems and needs described should invite interested workers, graduate students especially, to tackle the tasks that will lead to more and bettered techniques, a broadening of the range of work to which mappers may be applied, and an increase in the knowledge required for designing fluid mappers for particular jobs. Two phenomena occurring within certain distributed sources are described and named. It can at least be said that both are relatively unknown; and one of them may be new.

FLUID mappers may be described as fluid flow devices for visually simulating electrostatic, electromagnetic, heat conduction, and other analogous situations. This description is incomplete, but it will serve in an introductory way. The writer has described fluid mappers in detail in his first paper[1] on the subject, and it will be called the "first paper" herein.

Before Hele-Shaw did his work a half century ago, it was recognized that an ideal fluid (nonviscous) flowing in a thin flow space with suitable boundaries could theoretically simulate electrostatic and other fields. At any one location, the ideal fluid's velocities, taken across the flow space, would be constant. Whereas, with a real (viscous) fluid flowing in streamline or laminar fashion, the velocity at any one location would have a parabolic distribution. Hele-Shaw was the pioneer who showed, by his remarkable work, that a viscous fluid, with its parabolic velocity distribution across the space, would also yield an analogy. Hele-Shaw's methods were not carried on. His techniques, though admirably accurate, were costly and inflexible.

In fluid mappers developed by the writer, the upper plate (a piece of plate glass) is retained. But Hele-Shaw's lower plate is replaced by a slab made of artificial stone (dental stone), cast on plate glass to give it a flat surface. Thus great flexibility as to sources and sinks and as to slab boundary shape is attained, and with a medium offering cheapness and high accuracy. Also, the writer's invention of the sandbed as a distributed source or sink carries the fluid mapper into the extremely complicated realm of distributed source phenomena.

Dental stone powder costs only 15 to 20 cents a pound. Thin little slabs a few inches across take about a pound; larger slabs, one foot square and 5/8-inch thick, may take around four pounds. By spending a few dollars for some plate glass; a tray; some rubber tubing; two or three tanks; some brass pieces for molds, cores and barriers; some potassium permanganate; some dental stone powder; and a few other knickknacks–for a small expenditure, anyone can set up a fluid mapper laboratory for demonstrating a great variety of cases. With a further small investment in screen material and shotted metal, sandbed types of mappers become available.

Fluid mappers as now developed fall into three main types, all being represented in Figures 1 and 2.

The first type, shown at the right in both figures, is a slab without a sandbed. The sources amount to one or more simple wells of any shape or size. The bottom-up view, Figure 1, shows the plaster feet added to the plaster slab, the celluloid well bottom plastered on, and the connector tubes plastered into the well bottom.

The second type, at the left in Figures 1 and 2, is to operate as a slab with a sandbed. A suitable screen is mounted horizontally across the well, to support a sandbed above it, and having a plenum chamber below it. The plenum chamber has an aluminum bottom (it could just as well be celluloid).

The third type, at the top in both figures, is the isolated sandbed, a sandbed without a slab. Between the bottom and the screen is the plenum chamber. The sandbed is to be built above the screen.

A complete fluid mapper of the first type is shown in operation in Figure 3. The two wells are acting as sinks, their two connected tanks being nearly empty, with the right tank lower than the left. In the top view of this slab, Figure 4, the singular point has moved nearer to the large sink than where it is in Figure 3: this is because the tank levels were made the same, for the Figure 4 pattern.

Figure 5 shows a pattern obtained with a mapper of the second type. Here, the entire round sandbed area acts as a uniform distributed sink. The sandbed margin is not an isopressure line. This is very different from Figure 4, wherein the edge of a well acts as a boundary, it being an isopressure line.

Paper 50-267, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 20, 1950; made available for printing September 15, 1950.

A. D. Moore is Professor of Electrical Engineering, University of Michigan, Ann Arbor, Mich.

Figure 1 (left). The lower members of the three types of fluid mappers, shown bottom up. The upper member, the plate, is always plate glass

Figure 3 (right). A complete fluid mapper of the first type, in operation

The third type, an isolated sandbed, occurs in Figure 6. Here, the boundary of the sandbed is an isopressure line, it being open to the tray water.

For those who have not seen the first paper,[1] the foregoing will serve to describe the general nature of fluid mappers; and modifications not mentioned in the foregoing will receive attention further on. But space is not available here to set forth the numerous techniques needed for making and operating mappers in routine fashion. Many of these are covered in the first paper. Since that paper has appeared, the writer has continued intensive development work; many of the earlier techniques have been improved, some have been replaced, and a number of new techniques have been perfected. These will be included in a manual on fluid mappers and field mapping, now in preparation. And again, very little can be said here about the various analogous field phenomena that fluid mappers can be made to simulate. For this, the reader can consult the first paper; also the second paper[2] on soap film and sandbed techniques; and the third paper[3] in which fluid mappers are used to verify certain electromagnetic propositions.

Purpose of the Paper

The techniques already developed by the writer will serve for making and operating fluid mappers for portraying a great variety of the more ordinary situations. But looking ahead, the versatility of these devices indicates their wide adoption for a large range of diversified work. It appears inevitable that mappers will be built that will go beyond the limits within which the writer has worked. Others are adopting mappers, and others should join in contributing ideas.

The inherent errors, defects, and limitations of fluid mappers should be described; and where further invention, research, and development are needed on fluid mappers, the problems should be stated so that work can be started in proper directions. Plenty remains to be done. This paper will address itself to some of these problems.

Slab Permeability

Slabs made of dental stone are very slightly permeable. Since pressure differences must occur within the flow space, there is always a slight fluid leakage through the slab. The effect of this leakage would appear to be completely negligible whenever the slab has an open edge, with the flow space terminating directly in the tray water. In closed-edge mappers having an all-around barrier confining the flow to the slab face, it is possible to build up a considerable positive or negative pressure in the flow space, by having the general levels of the tanks much above or much below the tray. With a large, thin slab, it is barely possible that slab permeability might have to be guarded against, or taken into account. Slab permeability should be measured, and operating rules (if found to be needed) should be provided to insure operation within safe limits.

Slab Erosion

This is not mechanical erosion. It is disappearance of slab face material, due to its going into solution. Calcium sulphate, the main ingredient in dental stone, is slightly soluble in cold water, roughly in ratio of 2:1000. The rate of slab erosion in a fluid mapper has not been measured. The writer's experience indicates that erosion is irregular: the regions of higher flow space velocities erode fastest, which is to be expected.

For accurate fluid mapper work with plaster slabs, erosion trouble can be avoided by using a fresh-cast (or resurfaced) slab before erosion becomes serious. The thinner the flow space used, the more will flow space accuracy be altered by a given amount of erosion. The spacing-cubed law must be kept in mind here. As an illustration of the law: if a mapper is operated, first with a given flow space, then with a flow space of twice as much, the rate of fluid flow for the same pressure drop will be increased eight times.

Figure 2 (left). The lower members of the three types of fluid mappers

Figure 4 (right). Direct view of flow pattern. To produce this pattern, the tank levels were made equal

If erosion rates become known, we would know more as to how long a new slab could be operated without fear of it having become inaccurate.

A different attack is to stop erosion. There are at least three possibilities to look into. First, let the water used be made a saturated solution of calcium sulphate. Second, change the slab's surface from calcium sulphate to calcium stearate, which is nearly insoluble. Treating the slab with stearic acid might do it; or an application of any soft soap has been suggested. Third, the slab surface might be treated by painting it with a waterproofing material.

The writer has tried only the third expedient, and that in a limited way only. A synthetic rubber emulsion paint, Spred Satin, was used. If applied to a dry slab, it is a failure. When the slab is immersed, the water enters all surfaces except the painted surface; pushes the entrapped air out through pores in the paint; and, with build-up of capillary pressure, soon blisters the paint.

Spred Satin can be put on a wet slab, and will remain intact if the slab is kept wet. It should stop erosion. However, it takes a permanent pattern record, as is brought out later on. If a slab is to be used for a series of different operations, a confusion of recorded patterns would soon appear on the painted surface.

A fourth possibility might be worth a trial: dry the slab, then metallize the surface by metal spraying.

Slab Resurfacing

The writer has often reclaimed eroded slabs by a simple resurfacing technique. A large sheet of waterproof silicon carbide cloth, grit number 100 (Minnesota Mining and Manufacturing Company) is placed, face up, on plate glass. A little water is put on it. The wet slab, placed face down, is skated around with a random motion. When done, the loose plaster is washed off, excess water is wiped off, and a piece of plate glass is pressed against the slab face for testing. Where good contact is made here and there, a water film appears. A good distribution of such water films appears to indicate a high degree of flatness, and numerous operations of reclaimed slabs seem to indicate very good accuracy. However, all this should be looked into, and checked.

Slab Materials

Plaster, so far, is the prime material for slab-making; and the writer's guess is that it will remain so for most purposes. Patching plaster from the hardware store was used in the writer's early slabs. Plaster of Paris would do. These products, along with dental stone (artificial stone) are all basically calcined gypsum, calcium sulphate with two molecules of water. The writer usually calls all of these materials "plaster", even though the dental product is called "stone." When water is mixed with the powder, crystallization proceeds. Of all these, dental stone is the most highly developed, being hard, strong, smooth. Duroc, the latest dental stone powder, has a setting expansion of only one-half of one tenth of one per cent. With all of the numerous things that can be done in the casting process to alter shapes, plus the high workability of dental stone as to drilling or machining, plaster is most attractive. However, the tendency to erode may eliminate the plaster slab for some mappers; and then there is the tendency to stain.

Plastics, especially thermoplastics, should be given experimental attention. Plastics are priced high; but if a suitable thermoplastic that could be remolded many times could be found, that objection would be eliminated.

Metal slabs, such as aluminum, cast and machined, are attractive for purposes of high and continued accuracy. When a slab must be machined down to give a varying flow space (as mentioned later) it may be unwise to put machining time into a plaster slab which may erode seriously before the operation is finally completed.

Some metal slab techniques deserve attention.

Very Large Slabs

The writer's largest slabs are one foot square. These slabs are feasible in every respect, and are turned out and operated in routine fashion. The same routines ought to handle slabs up to 18 inches square, and perhaps 7/8-inch thick. But there is ample reason to think that still larger slabs will sometimes be needed. With increase in size, a point will be reached where the 1/4-inch plate glass on which a slab is cast may become distorted, unless it rests on a flat surface, or on supports that are in a plane and are at frequent enough intervals.

Next, how thick must a very large slab be, to be self-supporting in the tray, on its own feet, without distortion?

Another prospect is to cast slab sections, in rather accurate square or rectangular fence molds; then fit these sections together, edge to edge. This should be entirely feasible. It means placing accurate feet on the sections, so that the thickness from foot plane to slab surface is uniform. In the tray, a bottom piece of plate glass is placed first. The single slabs of Figures 1 and 2 are so prepared, and are so operated (with the off-slab spacer technique) in Figures 3, 4, and 5. Here again, with several sections making up a very large slab, problems of distortion of the bottom plate and the top plate would begin to enter. This problem calls for investigation.

Figure 5 (left). A mapper of the second type, a sandbed within a slab. The sandbed here acts as a uniformly distributed sink. Note the kernel

Figure 6 (right). An isolated sandbed: a fluid mapper of the third type. Note the kernel and the ridgeline

Figure 7 (left). A record slab

Figure 8 (right). With velocities high to get sharp pattern lines, inertia effects moved the break-away point nearly to the wing tip

Record Slabs

When a slab is sprinkled with potassium permanganate crystals to make the flow pattern visible, it is a "floor pattern." The colored streamlines are on or close to the floor of the flow, which is the slab surface. Slab staining follows, whereby a fairly good temporary pattern record appears on the slab face. Pink at first, and fairly definite, it soon diffuses when the slab is removed. Also, it changes to brown as manganese dioxide replaces the permanganate.

Excellent permanent record slabs are made by one of the writer's more recent techniques. Spred Satin 3400 White (The Glidden Company, Cleveland, Ohio) a synthetic rubber emulsion, is painted onto the wet slab face, after excess surface water is mopped off. A few minutes after painting, the paint is set well enough to permit operation. Whereupon, the permanganate of the colored flow lines chemically unites with the paint, and a record slab is produced. The record slab, Figure 7, was made on December 9, 1949. At this writing, just six months later, the record is as clear as ever.

The problem here is to change the painting job from an art to a science. Brush painting is somewhat tricky, and will at times cause enough irregularity of paint thickness, to affect the flow pattern by altering the flow spacing. For example, spray painting of Spred Satin has not been tried. It might be the answer.

Record slabs are very beautiful as well as useful. As to utility, they make fine classroom teaching aids. Also, making a record slab can often eliminate photographic steps, for the record slab pattern can be traced directly.

Fluids

Air, being free, perhaps deserves first mention in discussing fluids for fluid mappers. The writer has used air. Smoke streams are made by dotting the plate with hydrochloric acid, and loading the air with ammonia fumes. Results are not good. It is impossible to keep velocities down to within the streamline range, and not encounter high diffusion of the smoke streamers.

Tap water holds first place for most demonstration work with mappers, and will serve for accurate work when the conditions are right. In the quantities needed, water costs nothing; and when colored, is discarded. But flow space velocities must be made high enough to keep dye diffusion down so that a good pattern is achieved. In certain cases, this can mean that in going around corners or through narrow channels, local velocities can be great enough to bring in inertia effect, which spoils the laminar (streamline) flow in that region.

To point up the problem, refer to Figures 8 and 9 for flow around a Clark-Y airfoil section. In Figure 8, there is a good pattern with sharp lines; but the break-away point is very close to the wing tip. In Figure 9, velocities have been reduced; inertia effect has been greatly reduced; the break-away point has moved forward from the tip, and now is at, or close to, the singular point that would occur in a corresponding field of, say, heat conduction devoid of inertia. Thus, if we are solving for heat conduction or similar fields, we want the Figure 9 laminar flow; but it is bought at the expense of sharpness of line—the dye lines have more time for lateral diffusion.

A way out of the difficulty is to use a high-viscosity fluid such as glycerol, which Hele-Shaw used to get his beautiful lines. However, glycerol, (glycerine) is too costly for most fluid mapper work. Instead, Methocel (a Dow Chemical Company product) in water can be used to make a cheap high-viscosity fluid. Stanley Seltzer was the first to apply Methocel to fluid mapper work, when using mappers on an Air Forces heat transfer project in the Engineering Research Institute at the University of Michigan in 1950.

Methocel, a cellulose ether, is a colloid and is nontoxic. Of the several viscosity types available, the writer has used Methocel 1500 centipoises. Two per cent by weight of this, in water, gives a viscosity about 1,500 times that of water. It is then diluted to get any desired lower viscosity. (The company will send a booklet on Methocel.)

To see clearly why such a material as Methocel will get results, think of operating any such case as Figure 8, with water going fast enough to get a good pattern, but with undesired inertia effect at the corner. Then replace the water with Methocel solution having, say, four times the viscosity of water. Operate with the same head. Then the over-all flow rate will be one-fourth as much, thereby greatly reducing inertia effect. At first thought, it seems that we are as bad off as ever, for now a dye line has four times as much time in which to diffuse and become broad. But next, diffusion rate is inversely related to viscosity; and in theory, the pattern would have the same sharpness of line as when water was used. Anyone doing fluid mapper work should be fully aware of the possibilities of Methocel.

Investigation with a variety of mappers should be carried out, varying the shapes, the flow space, and the fluid viscosity. From this, rules might be written by which, in a given mapper, the viscosity needed to eliminate inertia effect could be known in advance.

Pattern Levels

Dye added to water increases the density, hence, dye lines tend to sink. When crystals are sprinkled on the slab

surface, the pattern starts out from the crystals at levels near the floor of the flow, and remains at such levels. This gives what we will call a floor pattern. Floor velocities being low, floor pattern lines move slowly, and tend to become broad due to lateral diffusion.

Dye crystals glued to the plate with Cutex form dye lines at high levels near the flow ceiling. They thus start out to form a ceiling pattern. Ceiling velocities being low, these lines tend to sink. But in sinking slightly, they get into higher-velocity levels in the flow space, and may be carried along as thin, sharp lines. Ceiling patterns are good patterns.

Dyes differ. The writer has tested methylene blue and permanganate crystals side by side, glued to the plate. In one straight-flow test, the permanganate line was heavy enough to sink to the floor within a quarter inch of travel; whereas, the blue lines remained as a sharp ceiling pattern for 8 inches, and would have gone much farther.

Methylene blue, made years ago in crystal form, is apparently quite unobtainable in that form today. Other dye crystals should be investigated with the hope of finding something better than permanganate for forming ceiling patterns.

Ideally, the middle pattern, half-way down across the flow space, would be the best from the standpoint of sharpness of line; for here, in the parabolic velocity distribution, velocities are greatest. We have now, no simple techniques for forming middle patterns.

Dyes and Dye Effects

Potassium permanganate is the best all-around material for most demonstrations, and for many applications of fluid mappers requiring good accuracy. It is cheap, and safe to work with. Its staining effect on slabs is easily cleared up,[1] and sodium bisulphite solution removes stains from the hands.

Methylene blue gives sharper lines, and the crystals last much longer. The hunt for a supply of these crystals must go on. It is safe, but it does permanently stain slabs, and the stain on the hands may last for some days. Still other dyes should be investigated for their good and bad properties.

One effect of the dye, still uninvestigated, is the effect on viscosity. No visual evidence has turned up, tending to show that this effect is ever serious. Nevertheless, it should receive attention.

Advancing Dye Front

Let a fluid mapper be operated without crystals, the flow being invisible. If permanganate dust is stirred into a tank feeding a source, the precolored water entering the flow space from the source will spread out over the slab with an advancing dye front. In the case of a long narrow sandbed in the middle of a large slab, the front has an approximately elliptical boundary. It is a very striking effect. No formal interpretation of this effect has yet been made. The effect undoubtedly has a meaning, possibly in terms of electromagnetic radiation. Someone should look into this effect.

Flow and Potential Control

When two or more tanks are used, connected to two or more wells, the problem of control of fluid flow or of potential (pressure) arises. The fluid mapper pattern must be made to conform to the conditions of the problem being solved. In many symmetrical cases, tank elevations need merely be adjusted until pattern symmetry prevails; but in more general cases, this expedient will not serve.

In many electromagnetic cases, for example, the rates of flow for the several wells must be proportioned to the corresponding currents which are setting up the magnetic field. Approximate determination of such fluid sources and sinks can be effected by making the long rubber tube connectors from tanks to wells equal in length and nominally equal in inside diameter; fixing tank levels to give the proper heads above or below tray water level will then fix the flows as desired. But rubber tubing is undependable for accurate work. Techniques should be worked out whereby the main resistance from tank to well mouth resides in a calibrated flow tube unit, having enough flow resistance so that all resistances outside it (including resistance offered in the flow space) can be largely or wholly ignored.

The other type of problem occurs when, say, the electrostatic field is being simulated, and isopressure lines bounding the several well edges must correspond to electrical potentials of charged bodies. The complete equipment that would enable the right setup to be made by a direct, or nearly direct approach, would seem to call for having a series of manometer tubes, with each tube connected to its well: tank levels could then be adjusted until the heads indicated at the manometer tubes would be as desired. Such additions are not attractive; for, unless thin and very accurate flow spaces are used (or a high viscosity fluid is adopted) the heads would be quite small. An alternative is to do without the manometer tubes, and approach the achievement of the desired relative pressures indirectly, by steps. This would be feasible if only two wells, connected to their own tanks, are present. Fixing one tank level throughout, set the second tank level arbitrarily, and get a pattern; then set at a new level, get another pattern; then repeat once more. Analyze each pattern locally, just far enough to deter-

Figure 9 (left). With lowered velocities, the inertia effects drop out and laminar flow prevails. Lines are more diffuse

Figure 10 (right). A semiobstacle case with flow spacings 2:1, representing permeability or conductivity ratio of 8:1

mine relative pressures of each. Plot relative pressure against tank level, to find the level needed to produce the pressure required.

In another form, a flow control problem occurs, as to flow equality, when a number of nominally equal sources are fed from a common plenum chamber. If the sources are small round holes, for example, what variations in diameter and depth are permissible?

Edge Effects at Isopressure Boundaries

In most fluid mapper work, the edge or boundary of a well, or the open edge of the slab, may be taken as the location of a boundary isopressure line. But in strict accuracy, pressure drop is not entirely confined to the flow space: a slight additional drop occurs where the space flow opens out into tray water or well water. The limiting isopressure line should therefore be taken as slightly beyond the flow space limit, at such locations. When is it necessary to do this and under what conditions, and where, exactly, should it be located, in terms of flow space thickness?

The problem is accentuated when a well must be used that is small in diameter, compared to the flow space thickness. In the general area over such a source or sink, there will be a large vertical component of flow. Where, in a given case, is the effective center of such a well, what is the well's effective diameter, and will these matters depend on whether a floor pattern or a ceiling pattern is used?

Edge Effect Along Barriers and Obstacles

To repeat, an ideal (nonviscous) fluid, having perfect slip at the fluid-solid interface, would give perfect simulations. A real, or viscous fluid, having no slip at floor and ceiling, and with its parabolic velocity distribution, also gives perfect simulations, as Hele-Shaw showed. However, when the flow is bound by barriers or obstacles, the perfection is marred by the fact that there is also no slip at these surfaces. Hele-Shaw used very thin flow spaces, and he does not appear to have discussed the edge effect that barriers and obstacles have on the flow pattern.

In the first paper[1] it is suggested that when necessary, this edge effect be allowed for approximately by cutting back the edges by one-fourth of the flow spacing. This is based on a velocity distribution analysis obtained by use of a sandbed mapper. This rule must be taken as an approximation, and as a means of getting a general pattern that is reasonably accurate. It cannot be taken as a cure for the difficulty, as far as flow very near to the edge itself is concerned. This edge effect needs thorough study. It may help to see into the problem if we note that, close to an edge, the flow patterns will be different at different levels.

Using an edge cutback, and a plain, or vertical edge on barrier or obstacle, would a floor pattern, or a ceiling pattern, or a middle pattern give the most accurate representation?

And then, there is another possibility. A study might show that if the edge is rounded with some curve, concave or convex to the flow, this, with a floor, or ceiling, or middle pattern, might give the best representation.

Stability

The necessity for using a thin flow space has been repeatedly emphasized. One reason, already covered, is to minimize edge effects. Another is to secure stability. With too great a spacing, the fluid wanders: upper-level patterns fail to coincide with lower-level patterns, when viewed from above. At this writing, no one knows the upper limit of the flow space thickness, for a given case, in terms of stability: we can only try it and see.

If we classify swirl effect[1] under stability, we can point to entry velocities from a connecting tube being so high in a large well, that the well edge is not an isopressure line: the flow pattern in the area near the well is spoiled. This can often be cured by crowding gauze into the lower half of the well.[1] The writer proposes trying a possibly more convenient cure: to drop fine, flexible metal chain into the well to cover the inlet tube and kill off unwanted inertia effect. A very small well acting as a source offers a stiffer problem: the smaller the source, the higher are the velocities near it, and the greater the tendency to ruin the desired streamline pattern. It is suggested that rounding the edge of the mouth of such a source might be beneficial.

The previous discussion of inertia effects, and their elimination by going to a fluid of higher viscosity, might just as well have been brought in here under the heading of stability.

Disturbing Influences

A dye crystal disturbs the flow. The flow may still be laminar around the crystal, but the crystal is a disturbing influence nonetheless. Can sprinkling of crystals ever be heavy enough to affect the general pattern seriously? We do not know.

A similar problem arises when spacers are laid on the slab to support the plate. How far does their disturbing influence reach, when a given degree of accuracy is desired?

A quite different kind of disturbing influence comes in if slabs of finite size must be used, when an infinite slab is in theory called for. Depending on the problem, the slab edge may be open, or it may be closed by a barrier, or it may be partly the one and partly the other. How close in can slab boundaries be brought, without unduly disturbing the central phenomena? This is a serious problem, and it needs attention.

Barriers

Barriers may be loose, or fixed. The loose barrier is laid on the slab, in location; and the plate is placed on it with care, so as not to shift it out of place.

The rubber barrier, cut from rubber sheet, is a very attractive loose barrier, in that complicated shapes are easily cut out. It should continue to receive consideration, even though the faults are serious. Rubber, or rubber-like sheet, is strictly unobtainable commercially, in a uniform thickness. Thus, the uniformity of flow space yielded by using the barrier as a spacer is somewhat untrustworthy, and must be checked for accurate work. Next, and especially in closed-edge cases (a complete barrier) flow space pressures are enough to cause very serious barrier leakage, unless plenty of *DC4* silicone grease is used for sealing.

Several-piece brass barriers, made from rolled brass strip and flattened by hand, are very convenient loose barriers for making up flow space areas of rectangular shapes, when an edge of the slab is open to tray water. Such an open edge insures low pressures across the barrier and leakage is often negligible even without sealant. The writer's experience has been confined to strips 1/16-inch thick. Such barriers are seen in Figures 8 and 9. Experience should be gained with 1/32-inch thickness, or even thinner, to learn about precautions needed, accuracy secured, and so on.

To insure accuracy and no leakage, even with large pressure heads on a complete barrier case, the writer has developed the fixed barrier. The slab is cast flat, as usual, but is made an inch larger all around, than the flow space area

needed. Thin plaster is laid down on the inch-wide barrier space. Spacers are laid on the flow space area. A piece of plate glass is then put down, with shifting movements, to squeeze the barrier plaster down to where the plate rests on the spacers. One must learn how to lay the plaster so that it squeezes in over the flow area somewhat. If the first attempt is a failure, simply wash off the added plaster and start right over again. As soon as possible, the plate is removed, and the trespassing plaster is trimmed back by narrow cuts, to the proper flow area border. This is done while the plaster is still soft. A little silicone sealant brushed onto the plate where it will rest on the barrier prevents all leakage. If positive pressure is put on the flow space, the plate may have to be weighted. With negative pressure (tank levels below tray level) a self-sealing job is secured. All this needs further experimentation, to make sure the process is invariably reliable as to spacing accuracy. Also, it is conceivable that careless spreading of sealant might have an effect on the spacing; and this should be investigated. In Figure 10, the slab has a fixed plaster barrier on three of its four edges.

Depressions

To simulate two media having differing dielectric constants, differing thermal conductivities, and so forth, a depression in the slab may be needed. One way to make a depression is to cast the slab flat; make it, with its feet, to accurate thickness; put it on the milling machine; and end-mill the depression into the slab face. Another way, suggested here but not yet tried, is to sweep it in: core a well in the slab when casting it, of the shape desired for the depression. With the slab face up, fill the well with plaster mix; then sweep the plaster as it sets with a sweeping tool, the blade of which extends down into the well to the right depth, and the extensions of which slide on the slab face. Any such technique has to be proved in before it can be trusted.

Metal slabs would be milled in any case; and depressions are then merely an extension of the milling job.

Semiobstacles

The airfoil section in Figures 8 and 9 is a complete obstacle, which we may simply call an obstacle: all flow goes around it. When a semiobstacle is present, Figure 10, some flow goes over or under it, depending on whether it is placed on the floor or ceiling. The effect is the inverse of that obtained by using a depression; but again, the two different flow spacings are used to represent two media.

Simple, reliable, and accurate techniques for making semiobstacles are much needed. Most of the ideas that will occur to one will be rejected. For example, it is a waste of time to cut a semiobstacle from rubber sheet, and lay it on the slab since it will not be flat; likewise for metal pieces, unless the area is quite small. Moreover, if an on-the-slab semiobstacle is reliably developed, then a ceiling pattern must be used: dye lines forming a floor pattern will be in that part of the flow that goes around, rather than over, the semiobstacle.

A floor pattern is used in Figure 10, in which the semiobstacle of celluloid is attached to the plate with acetone. Here, the two flow-spacings are 1:2, thus giving thermal conductivity ratios (for example) of 1:8. A larger view is shown in Figure 11. The celluloid attached to the plate is of one thickness. Spacers, made of two thicknesses of celluloid, were used in forming the fixed plaster barrier, thus achieving the 1:2 spacings mentioned.

These are simple techniques, but one of them is unreliable. The celluloid semiobstacle thus cemented to the plate might be quite uniform in thickness (after cementing) in one case, but not in the next. Let us hope that someone will work out something like this: dust the plate with a very thin coating of a thermoplastic in powder form; lay down the transparent semiobstacle; press it, with moderate heat; and get a waterproof bond of good transparency and negligible thickness.

Change of Flow Space More Generally Considered

The depression or the semiobstacle will often occur singly, and often in a small area surrounded by a much larger area of flow. Techniques suitable for making up such mappers may be too troublesome to apply to the more general case, in which there might be two (or more) spacings used, each occupying a considerable fraction of the area. For example, think of the magnetic problem offered by a motor pole piece, the air in gap and slots, and the teeth and core of the armature. The writer has made up a slab for such a case by greasing pieces cut from white 3 by 5 cards, with silicone *DC4* grease; sticking the pieces to the plate with the grease itself; laminating the cards to desired numbers of layers; casting the slab onto the plate thus built up; slipping the slab off when plaster is set; and then removing the card pieces. The slipping job is slow, and calls for use of a good deal of force, the grease being quite stiff. Results are crude. Such a slab is only a demonstrator rather than an accurate simulator, since uniform flow spaces are not to be achieved so easily.

Another way to alter the face of a flat-cast slab is, of course, to mill it down. Still another way is to add plaster to it in stages, using the technique described before for making fixed barriers.

It is to be hoped that when more workers apply their thinking to these problems, simple and accurate techniques for making any desired shapes of different flow spacings will be forthcoming.

Axial Symmetry Cases

A 3-dimensional field having an axis of symmetry may be said, in brief, to have axial symmetry. As shown in the first paper, some of these cases can be solved by fluid mappers. The type of mapper to be built depends on which of the two orthogonal systems is to be represented by the fluid flow. In the cross-axis type, where fluid crosses the axis, the flow spacing must be varied inversely with the cube root of the radius from the axis; in the pro-axis type, it must vary directly with the cube root of the radius.

In the writer's work so far, he has cast the slabs flat; then end-milled by steps or

Figure 11. A closer view of the semiobstacle pattern

Figure 12. Shotted metal samples. Left to right: tin, bronze, copper, nickel. Tin and bronze not suitable for sandbeds because of angularity

passes; then smoothed out the steps by hand-scraping the slab.

Two other possibilities should be given attention. First, if the steps or terraces left by end-milling are narrow enough, the flow space might be left terraced; and hand-scraping would drop out. How narrow should the steps be? Second, it is inviting to think of making metal molds, accurately finished, one of each type; and then casting the slabs on the curved mold surface. That part of it is simple enough. The difficulty comes in devising techniques for accurately adding barriers, wells, sandbeds, depressions, semi-obstacles, and so on. Here again, we need more ideas from interested and ingenious workers.

Quasi-3-Dimensional Cases

The preceding section dealt with axially symmetric three-dimensionals. The discussion prior to that can all be taken as bearing on 2-dimensional cases. We now come to cases that are neither of these. For example, think of current flowing in a reasonably flat metal sheet having constant resistivity, but with the sheet varying in thickness; or, think of oil flowing through a permeable underground bed, the permeability being uniform but the bed varying in thickness. In either case, the third dimension comes in. However, in both cases, it does not "get out of bounds": it is limited rather than unlimited. Fluid mappers, built to take the spacing-cubed law into account, can simulate such cases. We here call them quasi-3-dimensional cases.

If the thickness is smoothly varying, then a smoothly-varying flow space is called for. However, it would seem that if contour lines were laid out on a flat-cast slab (or metal slab) so that the slab could be milled down to terraced form in narrow enough steps and left that way, the uncertainties of hand-scraping could be eliminated.

Of course, such mappers would also apply to cases where the thickness of the actual case is uniform, but the property (such as resistivity, permeability, and so forth) varies; and further, they also could apply where both sorts of variations come in.

Sandbed Materials

The material used in the writer's first sandbeds was Standard Ottawa sand. It was so troublesome that it had to be given up. Glass beads must be mentioned here, tiny beads now available, and much used in Scotchlite. They deserve mention because others frequently suggest their use to the writer. But like sand, their specific gravity is such that a very slight water movement would serve to wash them out of place, when building the bed or when placing the plate.

Shotted metal was adopted to get away from the above difficulty. Plenty of Aerosol OT must be used as a wetting agent, to keep the metal granules from causing trouble by floating on the tray water. The metal granules should be heavy, round, bright, stable, and of uniform size. The ideal shotted metal for sandbeds has not yet been found.

We are talking here of loose sandbeds, each made up as needed. In the writer's opinion, the fixed sandbed of permanent type is just as unattractive, for practical reasons, as when the first paper was written.

Shotted Metal Sandbed Problems

Samples of four kinds of metal granules are shown in Figure 12. Tin, at the left, is very angular, and could not be trusted to pack uniformly. The bronze shot, next in line, is also too angular to be suitable. Third comes copper; and fourth, at the right, is nickel.

The nickel shot, being very round, smooth, and highly uniform, is almost self-packing. Under water, it flows into place with very little urging. Although it is darker than freshly cleaned copper, it is lighter than copper after the permanganate has had a chance to oxidize the copper. Nickel is much the best material yet found, and it is regrettable that it is not commercially available.

Shotted copper is none too round; not very smooth; lacks size uniformity; and has quite a few nonspheroidal particles. This at once raises the question of segregation. The threat of segregation should be avoidable by careful sifting to get size uniformity. If this is not done, very serious nonuniformity of the bed might at times occur because of segregation. Someone should look into the segregation problem, both to find the conditions of handling that may bring it on, and also those that will eliminate it. Along with this investigation, it would be desirable if a universal test for sandbed uniformity could be devised.

Making a good sandbed inherently brings in the packing problem. One phase of it pertains to arching that may occur next to the sandbed vertical walls, and in corners. This refers to the formation of large voids. Angular shot would be especially bad in this respect.

With reasonably uniform, round, smooth shot, major voids would not occur. But a localized packing problem remains, as an edge effect, where granules make contact with the sandbed wall. There are two possibilities. First, packing against the wall may very well give a relative absence of small local voids, thus cutting down on the vertical flow through the sandbed next to its margin. But second, the bed formation here might go the other way, creating an excess of voids next to the wall, and inducing extra and unwanted flow at the sandbed area margin. In the chemical field, a good deal of research has been done on the packing of various materials; but it appears that this particular problem has not been touched. It is important in sandbed work, and should be investigated.

In narrow sandbeds, a critical problem is to determine the minimum width in terms of number of grain diameters, that will still permit uniform packing. Obviously, a narrow sandbed only two or three grain diameters wide would result in irregular jamming of granules rather than uniform packing. What is the limit? In some cases, this limit will dictate the size of granule that must not be exceeded.

Sandbed—Flow Space Relationships

When a sandbed occurs within a slab, and a 2-dimensional field in one uniform

medium is being simulated, the flow space everywhere should be constant. If the sandbed is filled until the tops of the top granules just touch a plate placed directly on the slab face, then the flow space over the sandbed will be, in effect, slightly greater than the flow space over the slab: this is because of the presence of top voids. The thinner the spacing, or the larger the granules, the greater this effect becomes. The practical absence of flow refraction at the sandbed margin will indicate that the effect is negligible. However, this effect should be investigated, so that limits could be set in advance. Or again, in cases where the effect might be unavoidable and enough to worry about, the sandbed might be built high, by some fraction of a grain diameter, by using thin spacers on the slab when finishing off the sandbed. What fraction should this be?

The resistance to vertical flow up through the sandbed should, in theory, be infinite compared to the flow space resistance over the sandbed. The practice so far is empirical. Make a setup, as in Figure 5, and operate. Then cut the flow space, say, in half, and operate again.

If the previous pattern is duplicated, then all is well, and either flow space could be used, or any spacing in between. But looking ahead, we need to have work done on this problem of relationship, so that fluid mappers, even when pushed to extremes, can be designed with confidence. A theoretical-plus-experimental research on these flow resistance relationships should be carried out.

Another sandbed problem is to determine the minimum sandbed thickness, as related to grain size, that will give a uniform bed.

Still another arises from the fact that since fluid appears (or disappears) all over the sandbed area, there is a vertical component of flow in this part of the flow space. This component is foreign to the fields being simulated. Its effect in possibly distorting the pattern theoretically desired should be thoroughly investigated. In regions considerably removed from the kernel, or from the "ridgeline" to be mentioned further on, the horizontal flow component would be large compared to the vertical, and the effect should be very small. But near the kernel, the vertical component becomes relatively large; and at the kernel, it is relatively very great. Again, an empirical check like that mentioned above (halving the flow space and checking for pattern duplication) serves as a practical measure to lend assurance. But theoretical or experimental attacks should be used to look into this problem, going beyond the empirical stage.

Nonuniform Sandbeds

Up to now, only uniform sandbeds (constant in depth) have been discussed. Such sandbeds simulate uniformly distributed sources or sinks. But distributions of space charges, currents in conductor sections, and so on, may be nonuniform. Fluid source distributions over the sandbed should be varied accordingly. At this writing, no one has carried out any such work. However, it is easy to suggest three possibilities.

First, the continuous sandbed can be retained, but its depth can be varied at will by varying the screen depth. If sandbed depth is kept low compared to area, and if depth is not varied sharply, fluid flow density will vary nearly inversely as the depth.

Second, the sandbed can be compartmented, or divided into vertical and adjacent cells, all fed from a common plenum chamber. Using the same grain size, screen depths can be varied; or, using the same screen depths, grain sizes (using previously calibrated granules) could be varied.

The third prospect is to use the compartmentation idea, but with separate tanks connected to each cell, and with rate of feed adjustable by adjusting tank levels. All of the practical features of the techniques involved have yet to be worked out.

Sandbed Plenum Chamber

Ideally, the bottom of a sandbed (screen level) should be an isopressure surface; and this would be achieved by having a plenum chamber so large that pressure drops in it are negligible. Practically, the depth of a sufficiently good plenum chamber is far less than most would suspect. An easy practical test of a chamber is to have two connectors going to it, separated as far as possible. If, in switching the plenum chamber feed from one connection to the other, no pattern change is observed, the chamber is deep enough. However, looking ahead to possibly extreme conditions that may be required of some fluid mappers, the problem should receive experimental attention, at least.

The Kernel, and Lines of No Work

An apparent center within a distributed source or sink, where the lines seem to coverge, is clearly seen in Figure 5 or Figure 6. This is a well-known phenomenon. The name "kernel" has been applied to such a "center" or point, and the name is recognized.

Next, consider the flow lines of Figure 5. Interpret the pattern electromagnetically: then the sandbed area represents a conductor section with uniform current density. The lines of Figure 5, outside the conductor section, represent equipotential lines. But inside the current, the lines are not equipotentials. However, a point pole moved along any one line would require no work to be done upon it. Such lines—within a distributed source—have been distinctively called "lines of no work." This is also a well-known phenomenon, and the term is accepted. It may help to make the distinction between equipotential lines, and lines of no work, if we return to the fluid flow of Figure 5, and make the corresponding fluid flow distinction. Outside the sandbed area, the flow tubes are ordinary flow tubes, unaugmented. But within the sandbed area, we have what the writer calls augmented flow tubes. In a tube, the further we go out from the kernel, the greater is the flow in a tube section, due to the sandbed acting as a distributed source.

These two known phenomena within the distributed source are cited here, in order to lead up to two others, not so well known.

The Ridgeline Phenomenon

Distributed source fields are so extremely difficult to deal with theoretically, that very few solutions have ever been made, and very few good maps within such sources have been available. Also, until sandbed types of mappers came into existence, we had no way of setting up distributed source cases so as to look directly at the complete field representation. Thus, distributed source phenomena are quite unfamiliar to most, including most experts. Thus it happens that the writer has had the privilege of having an exceptional opportunity for

Figure 13. The point of inection, shown in the bar of the dumbbell. Nickel shot used in the sandbed

observing these phenomena, in operating numerous sandbed mappers.

One of the phenomena appears under certain conditions. It is a distinctive line, with the kernel located on this line. Such a line occurs in Figure 6, and it might be thought of as a "distributed kernel." In fact, a number of experts to whom the writer has shown such sandbed patterns have independently suggested this as a name. But another name will be proposed. The line under discussion is by no means well recognized; and a check with mathematicians and physicists indicates that it has not been named.

To lead to a name choice, think of having drawn the orthogonal system in Figure 6. The new lines would be isopressure lines. They would look like contour lines on a topographic map. Much to the point is the fact that if a soap film, stretched on the lip of this (emptied) sandbed ring is mildly inflated, its contour lines (as shown in the second paper) would correspond to the sandbed's isopressure lines. Whenever the sandbed has a line of the kind we are discussing, the corresponding soap film would have a ridge to correspond. Therefore, it is here proposed to call the line a "ridgeline."

The Point of Inaction Phenomenon

There is still another phenomenon. The writer has built sandbeds in which flow from one region tends to meet flow from another, the meeting place being also over the sandbed rather than outside it. A point of stagnation, or of no action, occurs. The "dumbbell" case, Figure 13, was especially built to illustrate this phenomenon. This isolated sandbed has a kernel in each lobe. The point of no action occurs in the middle of the connecting area.

There is the temptation to call this a "singular point within a distributed source." But to use "singular point" at all is to run the risk of implying that the field in this region is like the field about an ordinary singular point; whereas, it is very different.

This phenomenon, discovered in observing the operation of sandbed mappers, appears not to have been recognized; in fact, the possibility of its existence does not seem to have been suspected. To give it its own distinctive name, the writer proposes that it be called "point of inaction." Mathematicians are invited to the task of trying to work out the formal theory of this phenomenon.

Investigative Sandbed Work

With the foregoing instances as examples; with the recognition that probably, theory alone may never yield much insight into phenomena occurring within the distributed source except in the very simplest cases; and recognizing that sandbed fluid mappers offer a way of visually simulating these exceedingly complex phenomena, it may follow that some fruitful experimental work might be done with sandbeds, to gain insight, and possibly to discover additional phenomena.

Continuous Scavenging System for Hydrogen-Cooled Generators

D. S. SNELL
MEMBER AIEE

L. P. GROBEL
ASSOCIATE AIEE

Synopsis: This paper describes a new method for the operation of the hydrogen system of hydrogen-cooled generators which permits the use of untreated oil for supplying the shaft seals, thereby eliminating the need for the vacuum treating equipment formerly supplied with these generators. The new method provides for the removal of most of the air and moisture brought into the generator through the shaft seals by a system of continuous scavenging, through which the purity and relative humidity of the hydrogen in the generator are maintained at substantially the same values as are obtained with the vacuum treating system, and with a hydrogen consumption not significantly greater. Operating experience over a 4-year period with 24 generators of small and medium size, has demonstrated the reliability of the new system, and this system now is being applied quite generally to generators in all sizes except the very largest.

WITH the first hydrogen-cooled generators that were placed in commercial service, a system for vacuum treating the oil supplied to the shaft seals was provided. Vacuum treatment removes both gases and moisture from the sealing oil so that both the purity and dryness of the hydrogen in the generator are automatically maintained at high values. While this system has proved entirely successful, and is in current use with a large number of generators, the vacuum treating equipment is somewhat complicated, and also requires the operation and maintenance of a number of auxiliaries; hence, a study was early begun by the General Electric Company to simplify and improve the hydrogen system without sacrificing the many advantages of vacuum treatment.

The first approach to this problem was to develop a shaft seal having very low oil flow to the hydrogen side, so that the amount of air carried into the generator with the oil, using untreated oil for the seals, would be so small that a low rate of gas scavenging from the generator casing would permit the maintenance of the desired high value of hydrogen purity. However, even with the low rates of oil flow that were obtained with the type of shaft seal developed, the hydrogen consumption was several times that obtained with the vacuum system. This required either that a radically different type of shaft seal be used, or a different method of scavenging. Since the seal developed possessed several advantages over other types that would have a lower oil flow, it was decided to retain the seal and improve the method of scavenging. The method developed has been designated as the "continuous scavenging system"[1] and differs from the usual method of scavenging employed with hydrogen-cooled generators in that the gas is scavenged from the small annular space between the oil deflectors and the shaft seals, instead of from the much larger generator casing itself. This system was first applied to generators in 1946, and is described briefly in reference 2. Since the first installation, 24 generators using this system have been placed in operation (as of April 1950), and the scavenging system now is being applied quite generally to all hydrogen-cooled generators, except the very largest, built by the General Electric Company.

Operating Principle and Characteristic Curves

Fundamental Relations

If a hydrogen-cooled generator is operating with untreated oil supplied to the shaft seals, some of the air dissolved in this oil will be released to the hydrogen atmosphere, Figure 1. In order to maintain the hydrogen purity in the generator at a value satisfactory for safe and economical operation under these conditions, a certain amount of the impure hydrogen in the generator must be continuously discharged to atmosphere and sufficient fresh hydrogen must be added to maintain a constant gas pressure, this process being known as "scavenging." Considering first the conventional method of scavenging, in which gas is discharged from the generator itself, let it be required to determine the amount of fresh hydrogen q_0 cubic foot per hour of purity S_0 continuously required to maintain a generator hydrogen purity of S, for an air inflow of (a) cubic foot per hour. Since for the condition of constant gas pressure in the generator, the amount of hydrogen and air entering the generator must equal the amount of hydrogen and air leaving, the purity of the mixture entering the generator must equal S, as given by the equation

$$S = \frac{S_0 q_0}{q_0 + a} \tag{1}$$

from which

$$q_0 = \frac{Sa}{S_0 - S} \tag{2}$$

The above derivation, which was obtained from reference 3, is not strictly accurate, since it neglects the loss of gas by absorption in the sealing oil; however, as shown in Appendix I, the resulting equations are sufficiently accurate for most practical purposes.

Considering a generator operating with untreated oil supplied to the shaft seals,

Paper 50-268, recommended by the AIEE Power Generation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23-27, 1950. Manuscript submitted July 17, 1950; made available for printing September 20, 1950.

D. S. Snell and L. P. Grobel are both with the General Electric Company, Schenectady, N. Y.

The authors gratefully acknowledge the assistance of R. E. Gorman and F. T. Horan in connection with the development and design of the system herein described, and the assistance of Dr. Saul Dushman and Dr. Ferd E. Williams in the development of the equations given in Appendix II.

Figure 1. Schematic arrangement of shaft sealing system

resulting in an inflow of air with the oil of $a=0.4$ cubic foot per hour, let it be required to determine the amount of hydrogen of purity $S_0=1$ continuously required in order to maintain a purity of $S=0.97$ in the generator, by scavenging hydrogen from the generator itself. This amount from equation 2, would be

$$q_0=\frac{0.97\times 0.4}{1-0.97}=13 \text{ cubic feet per hour, or } 310 \text{ cubic feet per day}$$

Such an amount of hydrogen would usually be considered too large for economical operation.

If, however, the hydrogen purity in the generator is maintained by discharging to atmosphere impure hydrogen from the space between the shaft seals and the oil deflectors, (as in the arrangement shown in Figure 1), rather than from the generator casing, the term S in equation 2 will be replaced by Z, the hydrogen purity in the above space, and the amount of hydrogen required for scavenging will be appreciably less than that given by equation 2 since Z is significantly less than S. For a typical generator, operating at 0.5 pound per square inch hydrogen pressure, the purity difference $S-Z$ may be assumed as about 0.12. For the conditions of the above example, the amount of fresh hydrogen required to maintain a generator hydrogen purity of $S=0.97$, with gas at purity $Z=0.85$ discharged to atmosphere from the space between the shaft seals and the oil deflectors would be, from equation 2, with S replaced by Z,

$$q_0=\frac{0.85\times 0.4}{1-0.85}=2.27 \text{ cubic feet per hour, or } 55 \text{ cubic feet per day}$$

This amount is about one-sixth of that calculated for the same generator if scavenged by discharging gas from the generator casing, and is sufficiently low to make operation with this type of scavenging economical.

The large reduction in the amount of hydrogen required for scavenging by use of the above method in place of the conventional method of scavenging is the result of the generator construction; the provision of oil deflectors for preventing the entrance of oil and oil vapor into the generator, resulting in the separation of the space adjacent to the shaft seals from the generator itself by a partition acting to limit the diffusion of gases between the two sections, so that an appreciable difference in the hydrogen purities in the two sections can be maintained. (Although offering resistance to diffusion, the oil deflectors do not, however, materially restrict the flow of hydrogen from the generator into the seal chambers that is required for scavenging the impure hydrogen from the latter; the low rate of scavenging required causing negligible pressure drop across the annular space between the deflectors and the shaft. For a typical generator, a gas velocity of only about 10 feet per minute through this space is obtained.) By discharging impure hydrogen from the seal chambers to atmosphere, most of the air carried into the seal chambers with the sealing oil is removed before it can diffuse into the generator; hence, the amount of fresh hydrogen required to maintain a given hydrogen purity in the generator will be less than if scavenging were done from the generator itself.

Factors Influencing the Operation of the Scavenging System

In Appendix II, equations are derived for calculating the hydrogen consumption of a generator using the system here described, under various conditions of operation. It is shown that the gas consumption depends principally upon the following factors:

1. Rate of oil flow to hydrogen side of shaft seals. (F) or (Q)
2. The "apparent" solubilities of air and hydrogen in the sealing oil. (A) and (H)
3. The purity of the hydrogen in the generator. (S)
4. The "diffusion constant." (K)
5. The generator hydrogen pressure. (p)
6. The purity of the supply hydrogen. (S_0)

The apparent solubility of air in the sealing oil (A) represents the percentage of air by volume that is released from the oil as the latter enters the hydrogen atmosphere. This quantity is always somewhat less than the actual solubility of air in the oil which is the percentage of air by volume dissolved in the oil as would be determined from laboratory tests. Figure 2 shows values of air and hydrogen solubilities in a typical turbine oil at different temperatures, as determined from such tests. For oil at 45 degrees centigrade (representing the usual temperature of oil supplied to the shaft seals) Figure 2 indicates an actual solubility of 10 per cent for air and 6.4 per cent for hydrogen. In Figure 3 values of apparent solubility of air in the sealing oil as estimated from tests on a number of generators using the continuous scavenging system are shown. These values were calculated from equation 19 in Appendix II, the value of q_2 in this equation being estimated from the measured hydrogen consumption, an assumed loss of hydrogen by absorption in the oil, and an assumed value of generator hydrogen leakage. The values thus calculated range from 6 to 10 per cent, and are doubtless higher than the true apparent solubilities due to the nature of the assumptions made in their calculation. From tests on a 100,000-kva generator, in which fairly accurate measurements of the scavenging rate q_2 were obtained, apparent solubilities of air in the oil of between 4 and 6 per cent were calculated, see Figure 11. It is probable, therefore, that the apparent solubility of air in the sealing oil is between 50 and 75 per cent of the actual solubility.

Figure 2. Solubilities of air and hydrogen in light turbine oil as determined from laboratory tests. Oil viscosity 150 Saybolt universal seconds at 100 degrees Fahrenheit. Specific gravity 0.863

The apparent solubility of hydrogen in the sealing oil (H), (which represents the percentage of hydrogen by volume absorbed by the oil leaving the generator) is of minor importance in determining the

characteristics of the scavenging system, since this quantity affects only the amount of hydrogen lost by absorption in the oil, which is always small in comparison with the amount lost by scavenging. Tests on the 100,000-kva generator mentioned indicated an apparent solubility for hydrogen in the oil of 4.8 per cent, or 75 per cent of the actual solubility, which is a reasonable proportion, considering that about this same proportion of the air dissolved in the oil was found to be released to the hydrogen atmosphere.

The "diffusion constant" (K) is a factor representing the relative ease with which air may diffuse from the seal chambers into the generator casing through the clearance space between the oil deflectors and the shaft. It has the dimensions of cubic feet per hour and is determined by the effective axial length of one oil deflector (L), the area of the annular space between the deflectors and the shaft (for the two ends) (B), and the diffusion coefficient for air into a hydrogen-air mixture (K_a); the constant being expressed by the equation

$$K = K_a B/L \tag{3}$$

For an average gas temperature of 40 degrees centigrade, the coefficient of diffusion for hydrogen into itself, or into a hydrogen-air mixture containing more than about 75 per cent hydrogen (K_h), is 6.06 square feet per hour. From equation 28 in Appendix II,

$$K_a = K_h/3.8 = 6.06/3.8 = 1.6 \text{ square feet per hour}$$

hence

$$K = 1.6B/L \text{ cubic feet per hour} \tag{4}$$

From equation 4, using values of B and L obtained from the oil deflector drawings, the diffusion constant K has been calculated for a number of generators using the continuous scavenging system, giving the values shown in Figure 3. From equation 31 in Appendix II, values of K also have been calculated for these generators from readings of hydrogen purity and from the measured hydrogen consumption as obtained in tests. These values are shown in Figure 3 for comparison with values calculated from equation 4, and are observed to check the latter reasonably well, the differences obtained between the test and theoretical values being readily explainable by differences between the actual deflector dimensions and the drawing dimensions, due to wear or to slight inaccuracies in machining or assembly.

The relation between total hydrogen consumption q_0 and the diffusion constant K is obtained from equation 31 as

$$q_0 = \frac{K(S-Z)(3.8-2.85)}{(S_0-S)} \text{ cubic feet per hour} \tag{5}$$

For a specified value of generator hydrogen purity S, the hydrogen consumption is shown by equation 5 to be proportional to the product of the diffusion constant (K) and the purity difference ($S-Z$).

Calculated Operating Characteristics

From the equations derived in Appendix II, a number of characteristic curves illustrating the performance of generators using the continuous scavenging system have been prepared, which are given in Figures 4 to 10 inclusive. These curves show the calculated hydrogen requirements, also the purity of the scavenged hydrogen and the amount of hydrogen lost by scavenging, for different values of the generator hydrogen purity and pressure and for different rates of oil flow to the gas side of the shaft seals. Also, the influence of the value of the diffusion constant (K) and of the apparent solubility of air in the sealing oil (A) on the hydrogen requirements are shown. In the calculation of the various curves, hydrogen leakage from the generator casing has been neglected, the influence of this leakage on the generator hydrogen purity being shown by the equations of Appendix II to be small; also, a value of $S_0 = 0.996$ has been assumed.

In Figures 4, 5, and 6, the calculated hydrogen consumption is given for different values of generator hydrogen purity, gas pressure, and diffusion constant, at different rates of seal oil flow. Values of $H = 0.05$ and of $A = 0.10$ respectively for the apparent solubilities of hydrogen and air in the sealing oil have been assumed, a maximum value for the air solubility being used in order to obtain maximum values of hydrogen consumption. (These values for the solubilities were also used in preparing the curves of Figures 7, 8, and 10.)

To illustrate the use of the foregoing characteristic curves, a generator having an oil flow to the hydrogen side of the shaft seals of 0.5 gallons per minute ($F = 0.5$) will be considered, and the hydrogen consumption for hydrogen purities of 95 and 97 per cent will be determined for various conditions. Referring

(3) Apparent solubility calculated from test data assuming zero hydrogen leakage using equation 19. (4) Same as curve 3 except leakage of 5 cubic feet per day assumed

Figure 4. Calculated values of hydrogen consumption in operation at 0.5 pound per square inch hydrogen pressure for different values of generator hydrogen purity, and different purities of hydrogen discharged from seal chambers, at several rates of oil flow to gas side of shaft seals. For diffusion constant $K = 0.4$ cubic foot per hour and gas solubilities $A = 0.10$, $H = 0.05$

Figure 5 (left). Calculated hydrogen consumption of a generator for different values of the diffusion constant (K), for several assumed rates of oil flow to gas side of shaft seals (F) and for two values of generator hydrogen purity (S). For gas solubilities in oil of $A=0.10$, $H=0.05$. Operation at 0.5 pound per square inch hydrogen pressure assumed, except as noted

Figure 6 (right). Calculated hydrogen consumption of a generator at different hydrogen pressures, for several assumed rates of oil flow to gas side of shaft seals (F) and for two values of generator hydrogen purity (S). For gas solubilities in oil of $A=0.10$, $H=0.05$. For a diffusion constant of $K=0.4$ except as noted

to Figure 4, the curves of which have been calculated for a diffusion constant of $K=0.4$ cubic foot per hour and for a hydrogen pressure of 0.5 pound per square inch, the hydrogen consumption for the above seal oil flow is given as 36 cubic feet per day at 95 per cent purity and 50 cubic feet per day at 97 per cent purity. The corresponding purities of the scavenged hydrogen Z are given as 80.5 and 85 per cent, respectively.

Referring to Figure 5, which shows the influence of the value of the diffusion constant (K) on the calculated hydrogen requirements, for various rates of seal oil flow and for two different values of generator hydrogen purity and gas pressure, it is shown that for $F=0.5$, doubling the diffusion constant (that is, increasing K from 0.4 to 0.8 cubic foot per hour) increases the calculated hydrogen consumption by approximately 40 per cent, (or by less than half the percentage increase in the diffusion constant) for the two values of hydrogen purity and pressure considered. From this analysis, it may be concluded that a slight increase in the oil deflector clearances in service, causing a correspondingly slight increase in the value of the diffusion constant (K), would not increase the hydrogen consumption significantly.

Referring to Figure 6, showing the influence of hydrogen pressure on the calculated hydrogen consumption for different rates of seal oil flow and for two values of hydrogen purity and diffusion constant, it is shown that for $F=0.5$, doubling the absolute hydrogen pressure (that is, increasing the gauge pressure from 0.5 to 15 pounds per square inch) increases the hydrogen consumption by between 34 and 38 per cent, or by nearly the same amount as was shown in Figure 5 for a similar increase in the value of the diffusion constant K. The percentage increases in hydrogen consumption with increasing gas pressure shown in Figure 6 for generators using the continuous scavenging system, are much less than are obtained with generators using the vacuum system, if leakage is neglected; since with the latter system, the gas consumption (which is due only to absorption in the sealing oil, for no leakage) is proportional to the absolute gas pressure.

The influence of hydrogen pressure and diffusion constant, respectively, on the calculated purity difference ($S-Z$)–generator hydrogen purity less purity of scavenged hydrogen– is shown in Figures 7 and 8, for different rates of seal oil flow (F) and for $S=0.95$ and $S=0.97$. From Figure 7, the curves of which are calculated for a diffusion constant $K=0.4$, it is shown that for $F=0.5$, an increase in gas pressure from 0.5 to 15 pounds per square inch reduces the value of $S-Z$ for $S=0.95$ from 0.15 to 0.10, and for $S=0.97$, from 0.125 to 0.08; that is, doubling the absolute gas pressure reduces the purity difference by about one-third.

From Figure 8, the curves of which are calculated for a hydrogen pressure of 0.5 pounds per square inch, it is shown that for $F=0.5$, increasing the diffusion constant from 0.4 to 0.8 (that is, doubling it) reduces the calculated purity difference for $S=0.95$ from 0.15 to 0.105 and for $S=0.97$ from 0.125 to 0.088, or by about the same amounts as were obtained from Figure 7 for a similar percentage increase in the absolute hydrogen pressure.

The influence of the apparent solubility of air in the sealing oil on the calculated hydrogen consumption is shown by the curves in Figure 9, which are calculated for different values of seal oil flow, hydrogen purity and pressure, and diffusion constant K. An apparent solubility for hydrogen in the sealing oil of $H=0.05$ has been assumed. It is shown, for example, that in operation at 0.5 pound per square inch hydrogen pressure for $F=0.5$, $S=0.95$, and $K=0.4$, a 50 per cent reduction in the air solubility (that is, a reduction from $A=0.10$ to $A=0.05$) reduces the calculated hydrogen consumption by 25 per cent. The percentage change in gas consumption is thus shown to be only one-half as large as the percentage change in air solubility.

Figure 10 gives curves showing the calculated loss of hydrogen through scavenging for different values of the purity of the scavenged hydrogen (Z), for different rates of seal oil flow, and for hydrogen pressures of 0.5 and 15 pounds per square inch respectively. Apparent solubilities of $H=0.05$ and $A=0.10$ have been assumed. To illustrate the use of these curves, let $F=0.5$, $K=0.6$ and let it be required to determine the scavenging rate corresponding to $S=0.95$ at 0.5 pounds per square inch hydrogen pressure. Referring to Figure 8, the purity difference $S-Z$ for these conditions is 0.12, hence $Z=0.95-12=0.83$. Referring to Figure 10 for $F=0.5$, $Z=0.83$ at 0.5 pounds per square inch hydrogen pressure, the calculated hydrogen loss by scavenging is 39.6 cubic feet per

day. From Figure 5, the calculated total hydrogen consumption for the above conditions is 43.8 cubic feet per day, hence, the difference 43.8−39.6 =4.2 cubic feet per day must represent the loss by absorption in the sealing oil. From equation 12 in Appendix II, the latter loss is QHZ at casing pressure; hence, for the values of Q, H, and Z in the example, the absorption loss should be

$$0.5\times0.05\times0.83\times1.03\times1{,}440/7.5\times0.996 = 4.2 \text{ cubic feet per day}$$

which checks the value estimated from the curves.

Time Variation of Hydrogen Purity

When a generator employing the continuous scavenging system is first placed in operation, a considerable period of time is usually required for the generator hydrogen purity and the purity of the scavenged hydrogen to reach their final values. This is due to the large volume of the generator casing and the relatively slow rate of air inflow with the sealing oil. Figure 11 shows the time variation of the hydrogen purity values for a 100,000-kva 1,800-rpm generator operating with the scavenging system, during the first few weeks of operation, as obtained from tests. Since the scavenging rate was changed several times during this period, a considerable variation in the purity of the scavenged hydrogen was obtained; however, due to the large volume of the generator casing as compared with the volume of the seal chambers, this variation is shown to have had little effect on the generator hydrogen purity.

Equations have been derived for calculating the time variation of the hydrogen purity in the generator and in the seal chambers, respectively, during periods when these purities are changing. The equations and their derivation have not been included in the present paper. To check the accuracy of these equations, the purity values were calculated for the above generator for the initial period of operation for an assumed constant scavenging rate equal to the average rate actually maintained during this period. The calculated values are shown in Figure 11 and indicate a somewhat slower variation with time than was actually obtained. Considering, however, the considerable variation in the scavenging rate obtained in the test, the agreement between the test values of hydrogen purity and the values calculated for the assumption of a constant scavenging rate may be considered reasonable.

Design and Operation

Shaft Seals

The construction of the shaft seals used with most of the generators in service provided with the continuous scavenging system is illustrated in Figure 12. Each seal consists of a housing, supported on the outer end shield of the generator, in which are contained a pair of annular bronze sealing rings, made in segments, and having internal diameters slightly larger than the shaft diameter. The rings are held together radially and apart axially by a pair of coil springs attached to the upper and lower sections of the seal housing. Oil is supplied to the chamber containing the rings at a pressure about 4 pounds per square inch above the hydrogen pressure in the generator. This pressure creates an oil film between the rings and the shaft which prevents the outward leakage of hydrogen along the shaft.

The radial clearance on the shaft of the hydrogen-side seal ring is made considerably smaller than that of the air-side ring, this difference in clearances permitting a small oil flow to the hydrogen side of the seal, and a relatively large flow to the air side. The high air-side flow provides cooling for the rings so that their radial expansion is retarded and a low clearance on the hydrogen side, and, thereby a low oil flow to this side, can be maintained.

With some of the larger generators using the continuous scavenging system, a type of shaft seal having a single ring in place of a pair of rings, is supplied. The single ring is provided with a number of radial holes around the circumference, on the center line, through which oil from the seal housing is supplied to the inside bore surface of the ring, to provide a seal and supply cooling.

Shaft Sealing System

The arrangement of the shaft sealing system is illustrated diagrammatically in Figure 13. In normal operation, oil is supplied to the shaft seals from the bearing oil header, the flow being regulated by one of two differential pressure regulating valves arranged in parallel, one valve serving as a spare. At hydrogen pressures below about 10 pounds per square inch the bearing header pressure is adequate for supplying the seals directly,

Figure 7 (left). Calculated difference between generator hydrogen purity (S) and purity of the hydrogen discharged from seal chambers (Z) at different hydrogen pressures, for several assumed rates of oil flow to gas side of shaft seals (F), and for two values of generator hydrogen purity (S). Hydrogen loss calculated at purity of supply hydrogen $S_0=0.996$

through the regulating valves. Above this pressure, however, the seal oil pressure must be maintained through the operation of one of two seal oil pumps, acting as "boosters" for the bearing oil pressure. One pump is driven by an a-c motor and cuts in automatically if the hydrogen pressure exceeds about 10 pounds per square inch; the other pump is driven by a d-c motor and is arranged to cut in if the a-c supply is unavailable. In standby operation, the seal oil pumps are started automatically on loss of bearing oil pressure, which can occur if the turning gear oil pump is shut down. In such operation, the pumps are supplied from the storage tank of the sealing system, which in turn receives the oil discharged from the shaft seals.

In normal operation, the oil leaving the air side of the shaft seals mixes with the oil discharged from the generator bearings and passes to the main oil tank. The oil flowing to the hydrogen side of the seals enters the seal oil drain and passes into a horizontal section of piping below the generator designated as the seal drain enlargement. A large surface area is provided in the enlargement which permits most of the hydrogen entrained in the oil to be given up; the released hydrogen passing back to the seal chambers through the seal drain piping (as this piping does not run full of oil, ample space is available above the oil for the passage of gas, so that separate pipes for equalization of gas pressure between the drain enlargement and the seal chambers are unnecessary). The enlargement is divided by a transverse partition into two equal sections, which are connected below the oil surface through a loop seal. From a dome in the top of each section, a connection is made to atmosphere for scavenging gas from the generator. From the seal drain enlargement, the hydrogen-side seal oil passes to a float trap, which discharges the oil into the storage tank, from which it passes in normal operation to the bearing drain header. (In standby operation with no oil pressure in the bearing oil header, the gas side oil is returned to the seals by operation of the seal oil pumps, as previously explained.)

The storage tank, float trap, regulating valves, and seal oil pumps are mounted on a common base as shown in Figure 14. A panel on the side of the assembly carries gauges for reading the seal-oil and hydrogen pressures, the pressure switches for starting the seal oil pumps, and an alarm pressure switch for low differential seal oil pressure.

It will be observed from the foregoing description that the hydrogen-contaminated oil leaving the shaft seals does not become evacuated, as with the vacuum treating system, but normally passes into the bearing drain header. No operating hazard is thereby created, however, since the hydrogen-side oil flow from the shaft seals is so small in comparison with the total oil flow from the bearings of the turbine-generator set, that the dilution of the hydrogen in the sealing oil with air through mixing with the bearing oil results in a negligible percentage of hydrogen being present in the free air space in the bearing oil system. As shown in the section on Operating Principle and Characteristic Curves, the amount of hydrogen absorbed by the sealing oil of a generator is of the order of 4 or 5 cubic feet per day. Considering that the vapor extractor circulates many thousand cubic feet of air per day through the bearing drain system, it is evident that the creation of an appreciable concentration of hydrogen in this system is normally impossible. Tests made on a number of generators using the continuous scavenging system, with the vapor extractor shut down, have indicated a maximum concentration of hydrogen in the air atmosphere in the main oil tank of 0.3 per cent hydrogen in air, which is less than 10 per cent of the lower explosive limit of hydrogen in air.

Gas System

The system of gas control for a generator using the continuous scavenging system is illustrated diagrammatically in Figure 15. Control of the rate of gas scavenging from the two seal chambers is effected through needle valves at the hydrogen control panel. A flowmeter in each of the scavenging lines measures the scavenging rate from each end of the generator, while a gas analyzer in series with each flowmeter measures the purity of the scavenged hydrogen. A third analyzer measures the purity of the hydrogen in the generator casing. Connections to the latter analyzer from the high and low pressure zones of the generator ventilation circuit permit a circulation of gas from the generator through the analyzer with the generator operative, the rate of flow being measured on a flowmeter and adjustable by a needle valve. With the generator at standstill, a small amount of gas from the generator is continuously bled to atmos-

phere through the analyzer. The gas analyzers operate on the well-known thermal conductivity principle.

Other instruments on the control panel include: a fan pressure gauge, which, with the generator operative, gives a reading proportional to the density, and therefore to the purity, of the hydrogen in the generator; a dial thermometer reading the generator cold gas temperature; and two pressure gauges for reading the hydrogen pressure in the generator in operation at both 0.5 pound per square inch and at elevated pressures. A typical hydrogen control panel is shown in Figure 16.

Since the continuous scavenging system does not completely remove from the generator any moisture that may enter with the sealing oil, a gas dryer is provided. The dryer is connected into the high- and low-pressure zones of the generator ventilation circuit which permits gas from the generator to be continuously circulated through it. The dryer contains a quantity of activated alumina drying agent, which may be reactivated when moist, by energizing a heating coil in the dryer and operating a small blower to circulate air through it, the dryer being first isolated from the generator through the operation of shut-off valves.

A liquid detector is connected to the bottom of the generator casing which operates an alarm to indicate the presence of water or oil in the generator.

Alarm Signal System

An annunciator is provided at the hydrogen control panel which gives a visual and audible indication of any abnormal condition in the hydrogen system. The following alarm conditions are indicated by the signal system:

1. Machine gas temperature—high.
2. Machine gas pressure—low or high.
3. Hydrogen manifold pressure—low.
4. Hydrogen purity—low, or analyzer failure.
5. Differential seal oil pressure—low.
6. Liquid detector—full.
7. Seal oil drain—high oil level.

For a generator provided with a vacuum treating system for the sealing oil, a total of 12 alarm conditions are indicated by the alarm signal system as compared with seven for the system here described. This considerable reduction in the number of alarm conditions requiring supervision, obtained by the use of the new system in place of the vacuum system well illustrates the greater simplicity of the scavenging system.

Operating Experience

Hydrogen Consumption and Scavenging Rate

Data on operation of 22 generators using the continuous scavenging system are summarized in Figure 17. The hydrogen consumption for these generators at 0.5 pound pressure is shown to range from 32 to 90 cubic feet per day, the average consumption being about 50 cubic feet per day, which compares favorably with the consumption for generators using the vacuum treating system. The gas-side oil flow for the shaft seals of these generators is between 0.2 gallons per minute for the smaller sizes, and 0.7 gallons per minute for the largest 3,600-rpm generators. For the two 60,000-kw, 1,800-rpm units, the gas side seal oil flow is about 0.4 gallons per minute. Figure 17 also shows the reported average scavenging rates for the different generators as read on the flowmeters at the two ends of the generator, which are observed to range from 200 to 1,000 cubic centimeters per minute.

Many of these readings, however, especially the very high or very low values, cannot be regarded as accurate, giving values of hydrogen loss by scavenging either unreasonably low or high. Some of the readings, however, are apparently quite accurate. For example, generator number 5 had a reported average scavenging rate of 560 cubic centimeters per

Figure 12. Shaft seal for hydrogen cooled generator

Figure 13. Arrangement of shaft sealing system

minute at 86.4 per cent purity and a total hydrogen consumption of 41 cubic feet per day. For a flowmeter correction factor of 0.72, the hydrogen loss by scavenging, assuming hydrogen at 99.6 per cent purity, would be

$$2\times\frac{0.72\times0.864\times560\times0.051}{0.996}=35.6 \text{ cubic feet per day}$$

The difference between total hydrogen loss and the estimated loss by scavenging is $41-35.6=5.4$ cubic feet per day, representing the loss by absorption in the sealing oil and by leakage, which is a reasonable amount.

The hydrogen purity in the various generators is shown in Figure 17 to range from 95 to 99 per cent, the average value being about 97 per cent. The percentage of hydrogen in the scavenged gas is shown to range from 80 to 91 per cent, the average value being about 86 per cent. For generators using the vacuum-treating system, a machine hydrogen purity of 98 per cent or higher is usually maintained; hence, the average purity held with the scavenging system is slightly lower than that obtained with the vacuum system.

Moisture Content of Gas

The relative amounts of moisture being carried with the sealing oil into the various generators included in the above survey, are indicated approximately by the frequency of regeneration of the gas dryer, given in Figure 17. For generators 17 and 18, an appreciable amount of moisture was present in the turbine oil, due to abnormal operating conditions, which was reflected in having to regenerate the dryers daily. For the other generators, however, the dryers required regeneration at intervals ranging from 1 to 12 times per month, the average frequency being once a week.

Readings of relative humidity and dew point for the gas in four of the generators listed in Figure 17 are given in

Figure 14. Seal oil supply unit

*Dryer out of service.

quite as effective in removing moisture as in removing air from the generator. This fact also was demonstrated by the tests on generator number 21 which, with dryer out of service, indicated moisture content for the gas in the casing only slightly higher than was obtained with the dryer in service. For all of the machines listed in Table I, the dew point of the gas in the generator is well below the coldest practicable temperature for the water to the gas coolers, so that no possibility of moisture condensation is present.

Measurements of the relative humidity of the hydrogen atmosphere in a number of generators using the vacuum-treating system have indicated dew points between zero and 40 degrees Fahrenheit, which represents approximately the same range of values as shown in Table I. It is evident, therefore, that about the same degree of dryness for the hydrogen in the generator is obtained with either the vacuum or scavenging systems.

Operation at Elevated Hydrogen Pressures

A few of the generators using the continuous scavenging system have been operated at hydrogen pressures up to 15

Figure 15. Arrangement of gas control system

Figure 16. Hydrogen control panel

pounds per square inch, and the characteristics for such operation as given previously have been approximately realized. In most cases, however, an appreciable amount of leakage was present, so that an accurate check on the calculated characteristics could not be obtained. Generator number 20 in Figure 17, for example, which had a hydrogen consumption of 54 cubic feet per day at 0.5-pound pressure, operated with a consumption of 150 cubic feet per day at 15-pound pressure and was known to have several leaks at the higher pressure which could not be corrected during the tests. The purity of the scavenged hydrogen as obtained in tests on generators at elevated pressures, has always been somewhat higher than the values given by Figure 6; however, none of the tests was continued long enough for equilibrium values to be obtained and considerable variations in the scavenging rates were obtained, hence definite conclusions as to the accuracy of the calculations could not be made.

Conclusion

Operating experience with 24 generators using the continuous scavenging system, in place of the system of vacuum treatment of the sealing oil formerly used, has demonstrated that the scavenging system maintains the purity and relative humidity of the hydrogen within the generator at approximately the same values as are obtained with the vacuum treating system, and with a hydrogen consumption not significantly greater. Satisfactory performance of the scavenging system is shown to depend chiefly on the maintenance of the minimum practicable oil flow to the gas side of the shaft seals. The solubility of air in the sealing oil and the oil deflector dimensions and construction, also are shown to influence the operating characteristics of the system. The greater simplicity of the continuous scavenging system and its lower maintenance and operating costs, as compared with the vacuum treating system, are believed to compensate for a slightly greater hydrogen consumption, and to warrant the application of this system to generators in sizes considerably larger than those on which operating experience has been gained.

Appendix I. Calculation of Hydrogen Requirements for a Generator in which the Hydrogen Purity Is Maintained by Scavenging Gas from the Generator Casing

It is shown in the text that the amount of fresh hydrogen that must be supplied to an enclosure into which air is being continuously introduced, in order to maintain a constant hydrogen purity, is given by the equation

$$q_0 = \frac{Sa}{S_0 - S} \tag{2}$$

where

a = rate of inward air flow, cubic feet per hour at pressure in enclosure
q_0 = rate of hydrogen admission, cubic feet per hour at pressure in enclosure
S = per-unit hydrogen purity in enclosure
S_0 = per-unit purity of supply hydrogen

If it may be assumed that all of the air dissolved in the sealing oil of a hydrogen-cooled generator is given up as the oil from the seals enters the hydrogen atmosphere, the value of (a) in equation 2 may be approximately expressed as

$$a = QA/p \tag{6}$$

where

A = per-unit solubility of air in the sealing oil (cubic feet of air per cubic foot of oil at atmospheric pressure and supply temperature)
p = gas pressure in generator, atmospheres
Q = oil flow to gas side of shaft seals, cubic feet per hour

Substituting equation 6 in equation 2 gives the equation

$$q_0 = \frac{SQA}{p(S_0 - S)} \tag{7}$$

from which the amount of hydrogen required to maintain a specified value of hydrogen purity in a generator may be approximately determined, from the rate of seal oil flow and the value of the air solubility in the oil.

Equation 7 does not, however, take account of the loss of hydrogen in the sealing oil, and the fact that the air leaving the generator casing with the sealing oil is absorbed at casing pressure. To obtain a more exact equation for q_0, let

q_x = rate of discharge of hydrogen from generator through scavenging, including leakage, cubic feet per hour at casing pressure
H = per-unit solubility of hydrogen in sealing oil (cubic feet of hydrogen per cubic foot of oil at atmospheric pressure and supply temperature)

Also, it will be assumed that both hydrogen and air will be absorbed in the oil leaving the generator in proportion to the hydrogen and air solubilities. Then, for the condition that a constant gas pressure is maintained in the generator we have,

$$q_0 + QA/p = q_x + QHS + QA(1-S) \tag{8}$$

and for the steady-state condition that the amount of hydrogen entering the generator must equal the amount leaving we have,

$$q_0 S_0 = q_x S + QHS \tag{9}$$

Eliminating q_x between equations 8 and 9 gives

$$q_0 = \frac{SQ}{S_0 - S}[A/p - (1-S)(A-H)] \tag{10}$$

Which is the same as equation 7 except that in equation 10 the value of A/p is diminished by the quantity $(1-S)(A-H)$. For high values of casing purity, however, this term becomes negligible, hence equation 7 will be found sufficiently accurate in most cases.

To obtain from equations 2, 7, or 10, the amount of hydrogen required at atmospheric pressure, q_0 must be multiplied by (p).

In Figure 18, values of hydrogen consumption for different values of generator hydrogen purity are shown, as calculated from equations 7 and 10, for different values of seal oil flow and for assumed solubilities of hydrogen and air in the sealing oil of 5 and 10 per cent, respectively. The differences in the values of gas consumption calculated from the two equations are shown to be small. A comparison of the values of gas consumption as given by Figures 6 and 18, respectively, illustrates the advantage of the scavenging method described in the paper over the conventional method. For example, assuming a seal oil flow of 0.5 gallon per minute, a diffusion constant of $K = 0.4$, and a required generator hydrogen purity of 97 per cent, Figure 6 indicates values of hydrogen consumption obtained

with the new method of scavenging of 50 and 68 cubic feet per day at 0.5 and 15 pounds per square inch hydrogen pressure, respectively; while with the conventional method of scavenging, for the same conditions of oil flow and hydrogen purity, Figure 18 indicates a hydrogen consumption of 350 cubic feet per day at either 0.5 or 15 pounds per square inch hydrogen pressure, which is 7 and 5.2 times the amounts estimated to be required by the new method at 0.5 and 15 pounds per square inch pressure, respectively.

Appendix II. Calculation of Hydrogen Requirements for a Generator Using the Continuous Scavenging System

Referring to Figure 1, representing schematically the arrangement of the shaft seal at one end of a hydrogen-cooled generator, let

A, H, p, Q, and S_0 be as defined in Appendix I

S = per-unit hydrogen purity in generator casing

Z = per-unit purity of hydrogen in seal chambers (purity of scavenged hydrogen)

q_0 = rate of hydrogen admission to generator casing

q_1 = rate of gas leakage from generator casing

q_2 = rate of gas scavenging from the two seal chambers, including any leakage from these sections

q_3 = amount of gas from generator casing entering seal chambers, apart from amount entering by diffusion

qd_b = amount of hydrogen passing into seal chambers from generator casing by diffusion through clearance space between oil deflectors and shaft

qd_a = amount of air passing into generator casing from seal chambers by diffusion

The quantities q_0, q_1, and so forth are expressed in cubic feet per hour at casing pressure. The quantities q_2, q_3, qd_b, and qd_a represent the combined gas flows for both ends of the generator; also, the oil flow Q represents the combined gas-side flow from the two seals. To obtain cubic feet per hour at atmospheric pressure, the values of q_0, q_1, and so forth must be multiplied by (p).

It will be assumed, as in Appendix I, that all of the air dissolved in the sealing oil is given up as the oil enters the hydrogen atmosphere, and that both hydrogen and air are absorbed in the oil leaving the generator in proportion to the solubilities of these gases. (This assumption is pessimistic, giving higher values of hydrogen consumption than are actually obtained. However, any error in the assumption can be corrected for by proper choice of the values of A and H in the resulting equations.) For the condition of constant gas pressure in the generator we have*

$$q_0 + QA/p = q_1 + q_2 + QHZ + QA(1-Z) \quad (11)$$

Also, since under steady state conditions, the amount of hydrogen entering the generator must equal the amount leaving, we have

$$q_0 S_0 = q_1 S + q_2 Z + QHZ \quad (12)$$

Solving equation 12 for q_2 gives

$$q_2 = (q_0 S_0 - q_1 S - QHZ)/Z \quad (13)$$

*Actually, the gas pressure in the seal chambers must be slightly less than that in the generator casing, in order to have an outward gas flow q_3. However, the difference in pressures is too small to be considered here.

Figure 18. Calculated hydrogen consumption of a generator for which the hydrogen purity is maintained by scavenging from the generator itself (instead of from the seal chambers) for different values of the purity held. For several rates of oil flow to gas side of shaft seals (F). For gas solubilities in oil of $A=0.10$, $H=0.05$

Solid curves—calculated by exact equation 10 for 0.5 pound per square inch hydrogen pressure. Dashed curves—calculated by equation 10 for 15 pound per square inch hydrogen pressure. Dotted curves—calculated by approximate equation 7 for any hydrogen pressure

Figure 17. Data obtained in operation at 0.5 pound per square inch hydrogen pressure of 22 generators provided with continuous scavenging system

Curves (1) Generator hydrogen purity. (2) Purity of hydrogen discharged from seal chambers. (3) Average reading of scavenging flowmeters (right-hand scale). (4) Average daily hydrogen consumption (left-hand scale). (5) Frequency of reactivation of gas dryer (right-hand scale)

Figure 19. Calculated purity of hydrogen discharged from seal chambers (Z) for different values of the ratio of hydrogen consumption (q_0) to diffusion constant (K), and for different values of generator hydrogen purity (S) from equation 32, assuming $S_0=0.996$

Substituting equation 13 in equation 11 gives

$$q_9 = \frac{Z}{S_9 - Z}\left[QA(Z+1/p-1) + q_1\frac{(S-Z)}{Z} + QH(1-Z)\right] \quad (14)$$

For zero casing leakage equation 14 becomes

$$q_9 = \frac{ZQ}{S_9 - Z}[A/p - (1-Z)(A-H)] \quad (15)$$

Which is the same as equation 10 in Appendix I except that S is replaced by Z. Eliminating q_9 between equations 11 and equation 13 gives

$$Z = \frac{q_2 S_9 + QAS_9(1-1/p) + q_1(S_9 - S)}{q_1 + Q(H(1-S_9) + AS_9)} \quad (16)$$

from which the purity of the scavenged hydrogen may be determined from the scavenging rate q_2 if the casing leakage q_1 is neglected. Equation 16 also may be written

$$q_2 = \frac{S_9}{S_9 - Z}\left[QA(Z+1/p-1) - \frac{q_1}{S_9}(S_9 - S) + \frac{QHZ}{S_9}(1-S_9)\right] \quad (17)$$

from which the scavenging rate q_2 may be determined for a given purity of the scavenged hydrogen Z, if the casing leakage q_1 is neglected.

In deriving the foregoing equations, it has been assumed that all of the air dissolved in the sealing oil is given up as the oil enters the hydrogen atmosphere, and that hydrogen and air are absorbed by the oil leaving the generator through the seal drain lines in proportion to the hydrogen and air solubilities. The correctness of these assumptions may be checked by calculating the values of A and H from tests on an actual hydrogen-cooled generator, by the use of equations 11 and 13. For convenience in making such calculations, equation 13 may be solved for H, giving

$$H = \frac{q_9 S_9 - q_1 S - q_2 Z}{QZ} \quad (18)$$

and equation 11 may be solved for A, first substituting for H the expression given by equation 18, giving

$$A = \frac{q_1(1-S) + q_2(1-Z) - q_9(1-S_9)}{Q(Z-(1-1/p))} \quad (19)$$

Determination of the values of H and A from tests on generators using the continuous scavenging system, from equations 18 and 19, will give values of apparent solubility, which may be compared with values of actual solubility as determined from laboratory tests to show the extent to which the dissolved air in the oil is given up and hydrogen and air are absorbed by the oil in a given generator.

From equation 15, the total hydrogen consumption of a generator, neglecting leakage, may be determined for different values of the purity of the scavenged hydrogen Z and the system constants. To determine the corresponding purity of the hydrogen in the generator casing S, additional equations, taking account of diffusion between the generator casing, and the two seal chambers, are required. These will be derived as follows:

Letting the rates of mass flow by diffusion between the generator casing and the seal chambers, in pounds per hour, in the directions shown by the arrows in Figure 1, be M_{dh} for hydrogen and M_{da} for air, respectively, we have

$$M_{dh} = \frac{B}{L}\rho d_h K_h(S-Z) \quad (20)$$

and

$$M_{da} = \frac{B}{L}\rho d_a K_a(S-Z) \quad (21)$$

Where

B = cross section area of diffusion path, square feet (area of annular space between oil deflectors and shaft, two ends)

L = length of diffusion path, feet (axial length of one oil deflector)

d_h = density of pure hydrogen at atmospheric pressure, pounds per cubic foot

d_a = density of air at atmospheric pressure, pounds per cubic foot

K_h = diffusion constant for hydrogen, square feet per hour

K_a = diffusion constant for air, square feet per hour

(The constants K_h and K_a are assumed to be determined for the condition that both hydrogen and air are diffusing into a mixture that is predominately hydrogen, for example, 75 per cent or higher. For this condition, the value of K_h will be approximately the same as for pure hydrogen diffusing into itself, while the value of K_a will bear a fixed relation to K_h depending on the ratio of the molecular weights of hydrogen and air. Also, it will be assumed that the diffusion rate is uninfluenced either by the peripheral speed of the shaft or by the axial gas velocity in the clearance space between the oil deflectors and the shaft due to the flow of hydrogen to the seal chambers to make up the loss of impure hydrogen by scavenging. This assumption is based on the fact that both the shaft speed and the axial velocity of the hydrogen in the deflector clearance space are small in comparison with the molecular velocities of gases.)

Then

$$q_{dh} = \frac{M_{dh}}{\rho d_h} = \frac{B}{L}K_h(S-Z) \quad (22)$$

and

$$q_{da} = \frac{M_{da}}{\rho d_h} = \frac{B}{L}K_a(S-Z) \quad (23)$$

For the condition of constant gas pressure in the generator casing, we have

$$q_9 = q_1 + q_2 + q_{dh} - q_{da} \quad (24)$$

while for the condition that the amounts of hydrogen entering and leaving the casing are equal,

$$q_9 S_9 = (q_1 + q_2)S + q_{dh} \quad (25)$$

Eliminating $q_1 + q_2$ between equations 24 and 25 gives

$$q_9 S_9 = S(q_9 - q_{dh} + q_{da}) + q_{dh} \quad (26)$$

Substituting in equation 26 the values of q_{dh} and q_{da} from equations 22 and 23 gives

$$q_9(S_9 - S) = \frac{B}{L}(S-Z)[K_h(1-S) + K_a S] \quad (27)$$

Since the diffusion constants of two different gases with respect to a third gas are related to each other by the square root of the ratio of their molecular weights, we may write

$$K_h = \sqrt{14.4}K_a = 3.8K_a \quad (28)$$

Substituting equation 28 in equation 27 gives

$$q_9(S_9 - S) = K(S-Z)(3.8 - 2.8S) \quad (29)$$

Where

$$K = \frac{K_a B}{L} \quad (30)$$

This quantity is designated as the "diffusion constant" of the generator. Then from equation 29

$$K = \frac{q_9(S_9 - S)}{(S-Z)(3.8 - 2.8S)} \quad (31)$$

From this equation, the value of the constant K for a given generator may be calculated from tests from measurements of q_9, S, S_9 and Z.

Also, from equation 31

$$q_9/K = \frac{(S-Z)(3.8 - 2.8S)}{S_9 - S} \quad (32)$$

In Figure 19 curves of Z versus q_9/K, as determined from equation 32 are drawn for several assumed values of S. From these curves, it is possible to determine, for any value of S, the corresponding values of q_9/K and Z. Then with K known, values of Q may be determined from equations 14 or 15 for known values of A, H, and q_1. Or, assuming the oil flow Q and the value of K are known, and it is required to find q_9 for a given value of S, equations 14 or 15 may be used in conjunction with Figure 19 by a process of cut and trial, to determine q_9.

N. E. STARKEY
NONMEMBER AIEE

THE DEVELOPMENT of the combustion gas turbine as a new type of prime mover for power generation[1] has required the parallel development of suitable controls. The control scheme at present being used provides for semiautomatic starting and stopping of the unit, for speed and load control, and for prosection of the unit under abnormal operating conditions or in the event of malfunctioning of any component part. This paper describes the main components used in the control of General Electric gas turbines and how these components are combined to accomplish the above functions.

Characteristics of Gas Turbines

Several characteristics of gas turbines make the control problem different from that encountered with other types of prime movers. For instance, gas turbines are not self-starting and do not become self-sustaining until they reach about 50 per cent speed. A means must therefore be provided to crank the unit to firing speed and to assist acceleration after firing. A temperature control must be provided to limit the maximum and the rate of change of turbine inlet temperature to prevent damage to the turbine. Turbines that normally operate on bunker C oil must be started on diesel oil and transferred to bunker C at or above idle speed.

The starting sequence required, consists of several steps outlined briefly as follows:

1. Cranking the unit to approximately ten per cent speed to establish air flow through the combustion chambers.
2. Admitting the correct amount of fuel to the combustion chambers and applying ignition and booster air to initiate combustion.
3. Accelerating the unit after firing assisted by the starting motor.
4. Disengaging the starting motor when the gas turbine reaches self-sustaining speed.
5. Transferring from diesel oil to bunker C.

The stopping sequence required consists of the following steps:

1. Transferring from bunker C to diesel oil and operating on diesel oil for sufficient length of time to remove the heavy bunker C from the fuel pump, fuel lines, and fuel nozzles.
2. Shutting off the fuel supplied to the combustion chambers.
3. Rotating the unit after shutdown to allow proper cooling of all parts.

The unique characteristics of the gas turbine as outlined previously, made it desirable to provide partial automatic control on the first commercial gas turbines. In the first design of gas turbine control,[2] the various steps in the starting and stopping sequences were accomplished by manual operation of a control switch through six positions in sequence. Later designs, evolving from the first control, have retained the same basic control scheme but have been made more automatic. Operation of a master switch initiates the starting or stopping sequence which then proceeds automatically through the various steps required. Certain other changes have been made to improve reliability, to prevent possible damage by operational errors and to provide additional protection for the gas turbine under some abnormal conditions.

The first application of the automatic control has been to a 3,500-kw oil-fired unit.[3] The same basic control can, however, be applied to other sizes of gas turbines and also to natural gas fired units.

Control Components and Accessories

The following main components of the control system are mounted on the gas turbine:

Fuel Pump. Speed and load control of the gas turbine is obtained by varying the fuel flow to the combustion chambers. The required range of fuel flow is obtained by controlling the displacement of a variable displacement, piston type pump which is driven through gears from the gas turbine, Figure 1. The displacement or stroke of the pump determines the flow and this is directly proportional to a control oil pressure which is supplied by the fuel regulator. This control pressure will be referred to later as variable control oil (VCO). The fuel pump has six outlets with each outlet being supplied by three pistons 120 degrees apart in time phase and thus the pump splits the fuel flow among the six combustion chambers as well as setting the total flow.

Fuel Regulator and Electric Governor. The fuel regulator, Figure 2, is an electro-hydraulic servo-mechanism into which are fed a speed signal, an adjustable fuel limit and an exhaust temperature signal. The output of the fuel regulator is a VCO pressure in accordance with whichever of the above signals requires the least fuel flow.

The speed control is an electro-hydraulic governor similar to that used on Alco-General Electric diesel-electric locomotives.[4] The speed signal for the governor is obtained from a 3-phase tachometer generator with a permanent magnet rotor driven from the turbine shaft. The output of this generator is rectified to give a direct voltage which is essentially proportional to speed in the operating range. This direct voltage is applied to a circuit

Paper 50-269 recommended by the AIEE Power Generation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 18, 1950; made available for printing September 7, 1950.

D. C. HOFFMANN is with the General Electric Company, Philadelphia, Pa., and A. G. MELLOR and N. E. STARKEY are both with the General Electric Company, Schenectady, N. Y.

consisting of a solenoid operated pilot valve and a speed setting rheostat. The governor, as used in this application, has approximately a 2-to-1 speed range with speed being adjustable by varying the resistance of the speed setting rheostat by means of a split series field d-c motor mounted on the regulator. This motor also positions the adjustable fuel limit.

The adjustable fuel limit is used to set the correct VCO for starting and for acceleration. Above about 40 per cent speed the unit is under the control of either the speed governor or the exhaust temperature control and the adjustable limit is no longer effective.

The turbine exhaust temperature signal is obtained from a gas-filled bellows and tube assembly, mounted on the turbine exhaust hood and connected to the regulator by a capillary and bellows. This signal limits the VCO output of the regulator (and consequently the flow from the fuel pump) to prevent the turbine exhaust temperature exceeding a set limit. The exhaust temperature control also limits the rate of change of exhaust temperature by limiting the rate of change of VCO pressure. No control of the rate of decrease of exhaust temperature is possible under emergency conditions since it is necessary to shut off the flow of fuel as rapidly as possible.

Stop Valve. The stop valve is a solenoid operated valve located in the inlet line to the fuel pump.

Overspeed Governor. This is a flyball type governor, Figure 3, which operates a valve to reduce VCO pressure in the event of overspeeding of the unit. It also incorporates a switch, set to operate at 110 per cent speed which will act to close the stop valve and shut down the unit.

Figure 1. Variable displacement fuel pump

Fuel Transfer Valve. This is a motor operated, 3-way valve used to transfer from diesel oil to bunker C and vice versa. Since the diesel oil used is approximately at room temperature while the bunker C is at approximately 225 degrees Fahrenheit, the transfer from one fuel to another must be made gradually to avoid rapid temperature changes in the fuel pump.

Flame Detector. The flame detector consists of a thermopile which has several thermocouples exposed to the radiation from the flame in the combustion chambers and an equal number of thermocouples exposed to compressor discharge air temperature. The output from this thermopile is amplified and used to actuate certain relays in the turbine control panel.

Ignition System. Two 60-cycle 110/-15,000-volt ignition transformers and two spark plugs are used to initiate combustion. Fuel in the other four combustion chambers is ignited through cross-fire tubes between adjacent combustion chambers. The spark plugs used are of a retractable type which are extended into the combustion chambers by springs when the gas turbine is at rest or operating at low speeds. As the turbine accelerates to idle speed, the increased air pressure in the combustion chambers forces the spark plugs to a retracted position away from the flame.

Atomizing Air Compressors. This is a 2-stage centrifugal compressor driven from the gas turbine. Air, extracted from the main compressor discharge, is cooled, compressed in the atomizing air compressor and supplied to the fuel nozzles for fuel atomization.

A booster air compressor is used to increase the atomizing air flow during starting of the gas turbine. This is an induction motor-driven compressor which is shut down when the main atomizing air pressure is sufficient.

Lubricating Oil Pumps. This is a centrifugal type pump driven from the gas turbine. This pump is capable of supplying all the lubricating oil required above about 75 per cent speed of the gas turbine.

An a-c motor-driven auxiliary lubricating oil pump is provided to supply lubricating oil for starting and also is started automatically in case of failure of the main lubricating oil pump.

A d-c motor-driven emergency lubricating oil pump is provided as a backup in case of failure of both the main and auxiliary lubricating oil pumps.

Figure 2. Fuel regulator

Starting Equipment. A 2-hp a-c motor-driven turning gear is used to start the gas turbine from rest in order to establish an oil film in the bearings before starting the main cranking motor. The turning gear is also used to rotate the unit to insure proper cooling. The turning gear drives the turbine shaft through gears and is engaged by means of a solenoid.

The main cranking motor is an 1,800-rpm wound rotor induction motor which drives the turbine through a step-up gear and clutch. Switching of the secondary resistors of this motor gives the correct torque characteristic for cranking the unit up to firing speed and for assisting acceleration to idle speed after firing.

Figure 3. Overspeed governor

Figure 4. Turbine control board, front view

MISCELLANEOUS EQUIPMENT

A gas-filled tube mounted in the turbine exhaust hood protects the turbine against excessive temperatures.

Several pressure and temperature switches are provided in the lubricating oil, fuel oil, and atomizing air systems to indicate abnormal conditions.

Electric pressure transmitters are used to give an indication of lubricating-oil pressure and fuel-oil pressure at the turbine control panel.

A high-low level indicator with alarm contacts is provided in the lubricating-oil tank.

Turbine Control Board

The turbine is controlled from the main duplex control board located on the turbine room floor. The board consists of stationary front and rear panels with top plates and an end enclosure with hinged door, all bolted together to form a rigid self-supporting structure. The control board is bolted to and forms part of the a-c switchgear for the generator. Instruments, recorders, annunicator, and control switches are mounted on the front panels, Figure 4. Sequence and protective relays are mounted on the rear panels, Figure 5.

In an installation of this type, many conditions must be checked before the turbine can be started safely. Starting and stopping the unit includes steps that must be performed in correct sequence and at proper time intervals. Automatic control is provided to relieve the operator of most of the routine and responsibility of performing and checking each step in the starting and stopping sequences. The indications to start and stop the unit normally are given by a master control switch on the duplex control board.

In designing the control and protective circuits, principles well established in other applications of automatic control were used to full advantage. Such principles include the use of a station battery, selective fusing of control and trip circuits, and interlocking of sequence and timing functions to obtain maximum reliability, safety, and continuity of service.

Protective devices are grouped so that they are selective in regard to the manner in which the unit is shut down, as will be detailed later.

Automatic Starting Sequence

All automatic control functions are directed by a master relay that must be energized by the master control circuit before the unit can be started. This master circuit includes contacts of protective relays and other devices that check that normal operating conditions exist before the starting sequence can begin. If normal conditions exist, the operator may start the unit by means of the master control switch.

While the actual starting sequence is automatic, there are a number of operations and checks that the operator must make before starting and during the starting sequence. If it is assumed that control and auxiliary power are available and that all protective devices and annunciator drops are in their normal reset positions, the following are the specific steps that the operator must take to put the unit on the line:

1. Check that the operation selector switch is in the automatic position to permit the starting sequence to take place without interruption. Other positions of this switch are used for test purposes, as will be described later.

2. Check that the fuel selector switch is in the desired position. With the switch in the bunker C position, the turbine is started on diesel fuel and transferred to bunker C fuel automatically at the proper time in the sequence. The switch may be put in the diesel fuel position for continuous operation on diesel fuel.

3. Start any required cooling water and fuel oil pumps and check temperature and pressure of fuel oil. The diesel fuel oil must be at proper operating pressure before the turbine can be started. In an emergency, the turbine can be started and run on diesel oil until bunker C oil at proper temperature and pressure is available.

4. Start the auxiliary lubricating oil pump to provide oil pressure during starting. After the turbine has come up to speed, the direct connected oil pump will supply lubricating oil at the required pressure, and the auxiliary oil pump can be shut down.

5. Close the circuit breaker feeding the d-c emergency lubricating oil pump so that the pump will be ready to start at any time upon failure of normal pressure, whether supplied by the direct connected pump or by the auxiliary pump.

6. Operate the master control switch to the start position. This causes the turbine to start automatically (see subsequent details).

7. Stop the auxiliary lubricating oil pump when the turbine is up to approximately full speed.

8. Synchronize the generator to the bus and pickup load.

When the operator turns the master control switch to the start position in step

* Also automatically transfers fuel supply from bunker C to diesel oil.

6 above, the following operations take place automatically and in the sequence indicated:

1. The green lamp above the switch is extinguished and the yellow lamp is lighted. The green lamp indicates that conditions are proper for starting the unit (see Protective Operation). The yellow lamp indicates that the unit is in the process of starting.

2. The turning gear motor starts and turns the turbine shaft at 2 rpm.

3. The cranking motor starts and accelerates the turbine to about ten per cent speed. The cranking motor is connected to the turbine shaft by a solenoid engaged overrunning clutch that is energized before the motor is started.

4. The combustion chambers are purged of possible explosive mixtures by allowing the cranking motor to drive the turbine at about ten per cent speed for several minutes.

5. The regulator positioning motor is adjusted to provide a fuel setting proper for firing.

6. The fuel valve opens, the booster air compressor starts, and ignition is turned on. Booster air pressure is used to insure complete atomization of the fuel at the low speed at which the turbine is running.

7. When the turbine fires, the flame detector operates to cause the sequence to proceed. If the turbine does not fire within a predetermined time, the ignition, fuel, and booster air are cut off. The turbine runs at 10 per cent speed for a definite time to purge the combustion chambers, after which the ignition, fuel, and booster air are turned on again. If the turbine does not fire after the second such attempt, it is shut down completely and locked out (see Protective Operation).

8. When the flame detector indicates that the turbine has fired, the speed of the cranking motor is gradually increased by shunting out secondary resistance and the turbine is accelerated by the cranking motor and by its own power. The ignition is cut off.

9. Fuel is increased and as the turbine comes up to self-sustaining speed, the cranking motor disengages and shuts down. The booster air compressor also is shut down.

10. When the turbine reaches about 80 per cent speed, the fuel transfer valve gradually changes the fuel supply from diesel to bunker C. The yellow lamp is extinguished and the red lamp is lighted to indicate the end of the starting sequence.

When the end of the starting sequence is indicated by the red lamp, the operator should shut down the auxiliary lubricating oil pump, as the direct connected pump is capable of supplying sufficient pressure. The operator may now synchronize the generator, connect it to the bus, and load it in the usual manner.

Normal Shutdown Sequence

The normal shutdown sequence of the unit is almost entirely automatic. The definite steps to be taken by the operator are:

1. Decrease load to zero and disconnect the generator from the bus in the usual manner.

2. Operate the master control switch to the stop position. This initiates the automatic stopping sequence (see subsequent details).

3. Stop the motor-driven fuel supply pumps.

4. At the end of the automatic stopping sequence, open the circuit breaker to the d-c emergency lubricating oil pump so that the pump will not start when step 5 is taken.

5. Stop the auxiliary lubricating oil pump and cooling water pumps.

When the operator turns the master control switch to the stop position in step 2 above, the following operations take place automatically in the sequence indicated:

1. The red lamp is extinguished and the yellow and green lamps are lighted. The yellow lamp indicates that the stopping sequence is in progress. The turbine can be restarted any time that the green lamp is on and during cooldown.

2. The diesel-fuel supply pump starts and the fuel transfer valve gradually changes the fuel supply from bunker C to diesel oil.

3. The turbine runs for several minutes on diesel oil to purge the lines of the heavier bunker C oil. At the completion of this run, the green lamp goes out.

4. The fuel supply is gradually reduced until the flame goes out. The fuel valve then closes completely.

5. The turbine coasts to a stop.

6. The turning gear motor starts and the turbine is rotated for several minutes to allow proper cooling of all parts.

7. The turning gear motor stops and the turbine coasts to a stop. The yellow lamp is extinguished and the green lamp is lighted to indicate the end of the stopping sequence.

Test Operation

An operation selector switch is provided for interrupting the starting sequence at several selected points for test purposes, or to facilitate calibration of protective and control devices. The switch has the following positions: manual; turning gear; crank; fire; speed control; and automatic.

During normal operation, the selector switch is in the automatic position and the sequence is not interrupted. In the manual position, various turbine accessories that ordinarily start automatically can be started and stopped only by individual control switches. The devices that can be so operated are: turning gear motor (jogging only); booster air compressor motor; governor positioning motor; ignition transformers; and fuel transfer valve.

The other positions of the selector switch indicate points at which the sequence can be stopped. For example, in crank position, the automatic starting

sequence progresses only to the point where the turbine is cranked at 10 per cent speed by the cranking motor. The operator can set the switch in any of the four positions and the starting sequence will proceed to that point, or the operator can progress from point to point.

Protective Operation

The turbine and its accessories are protected against damage due to any abnormal condition likely to occur in an installation of this kind. The turbine is prevented from starting unless all conditions affecting its operation are normal. Contacts of the devices that check these conditions are connected in series with the master control relay. Other protective devices shut down the turbine if any trouble develops while it is in operation. In order to obtain maximum continuity of service, which means not shutting down the turbine unless necessary, the protective devices are grouped according to the seriousness of the abnormal condition.

Group I includes devices that prevent the turbine from starting.

Group II includes devices that detect trouble of relatively minor nature. These devices operate an annunciator and sound an alarm so that the operator can take the necessary steps to correct the trouble before a shutdown becomes necessary.

Group III includes devices that detect serious trouble that requires immediate shutdown of the turbine. In an emergency such as this the fuel is shut off immediately. The normal shutdown sequence is not used, that is, the fuel lines are not purged and the turbine is not cranked for cooling. The operator must take appropriate action, depending upon circumstances.

There may be some differences of opinion among operators and gas turbine engineers as to the grouping of the various protective devices. Operating experience will eventually determine the best practice. Table I is the grouping used at the present time.

Control of Auxiliary Motors

Conventional motor control equipment is used for the various auxiliary motors referred to in the description of the turbine control. Additional interlocks are provided as required to enable these motors to be started and stopped at the correct points in the sequences. Thermal overload relays in the motor circuits are used to give a warning in case of overheating of a motor.

In addition to the motors directly associated with the operation and control of the gas turbine, a complete gas turbine generating station requires motor-driven cooling water pumps, diesel-oil supply pumps, bunker C oil supply pumps and bunker C centrifuges. This equipment and its control is all of conventional design.

Modification of Control for Gas Fired Units

The turbine control described is designed for a liquid fuel-fired gas turbine unit. The modifications required to adapt the control for a gas-fired unit are minor and result in some simplification. Fuel flow for a gas-fired unit is determined by the opening of a gas control valve. The same fuel regulator is used but the VCO output of the regulator controls the position of the gas control valve instead of the displacement of the fuel pump. No atomizing air compressors are required on gas-fired units and the control for transfer of fuel from diesel oil to bunker C is eliminated. No fuel supply pumps or centrifuges are required, but, in cases where the available gas pressure is too low, a fuel gas compressor is required.

Automatic Gas Turbine Stations

The possibility of building completely automatic, unattended gas turbine generating stations was taken into consideration in the design of this control system. The modifications and additions required for an unattended gas-fired station are minor but an unattended oil-fired station presents some additional complications mainly in the fuel handling, heating and centrifuging equipment required for the bunker C oil.

Conventional supervisory equipment can be used for remote control and telemetering of any number of quantities desired.

Discussion

Joel W. Blake (Oklahoma Gas and Electric Company, Oklahoma City, Okla.): The authors have presented a very complete outline of the control of gas turbines with particular reference to a system for starting and governing as used on General Electric Company gas turbines burning either liquid or gaseous fuel.

The control for a gas turbine is quite complex. The starting phase involves many variables such as purging; control of exhaust temperature (both rate of change and top limit) acceleration; supervision of flame; and so forth. When up to speed and on the line, all of the features of steam turbine governing must be covered, with the addition of exhaust temperature control and supervision of flame.

My discussion will be limited to the control as applies to the simple cycle unit installed at Belle Isle Station burning natural gas only.

At our insistence, particular consideration was given to protection against any possibility of explosion occurring during the starting phase. Originally, a purging blower was included to remove any gas fuel which might pass the closed control valve while the unit was shut down. After a few starts, it was apparent that this device was unnecessary and it was removed. The present practice is the same as is followed on our gas fired boilers, namely, when the unit is down a lubricated cock in the gas supply to the unit is closed and the vent down-stream from this valve is opened to atmosphere.

Another precautionary step in the starting cycle was the inclusion of a purge period. It was felt that if such a step were included, the exhaust duct system and recuperator would be entirely scavenged and when the unit did fire, there would be no possibility for an explosion to occur. The duration of this purging period is six minutes and we have seen no occasion to alter the length of time.

The governing of the unit has been very good. Being steam turbine minded, we were quite skeptical of the electro-hydraulic governor used. It was felt that any type of turbine should have a governor which could be "worked on" with a wrench and screw driver rather than an electrical analyzer set and turning of rheostats or changing condensers. We must admit though, that the governor is a good one and our concern was unfounded. This device, being one with which our men were unfamiliar, required a complete set of instructions which we now have. We still have the self-satisfaction, however, that the last line of defense, the emergency governor, is of the fly-ball type.

Protective devices have functioned as intended, with a minimum of trouble. One unit, the dual flame detector, originally was of rather short life, however, improvements in mounting have greatly prolonged their life. The unit functions only if both the detectors go bad. This has happened only once to date and since they are the "fail-safe" type, it merely caused a shutdown.

The quality of the entire starting and gov-

erning system is demonstrated by pointing out that it has functioned perfectly through over 100 starts and almost 9,000 hours of operation. It also should be pointed out that the maintenance on the entire control equipment is work for a high type electrical technician rather than an unskilled man.

Our unit can be called a semiautomatic job with complete supervision and protection of all important points. It is easy for us to foresee that little added equipment would be necessary to make it fully automatic. As such, there is no reason why the unit should not function entirely by remote control.

Thrust Bearing Problems and Their Solution on Turbine-Generator Units and Auxiliaries of the Consolidated Edison System

JOHN M. DRISCOLL
NONMEMBER AIEE

H. C. OTTEN
MEMBER AIEE

IT HAS BEEN our purpose in preparing this paper to describe a few of the thrust bearing failures which have occurred in the plants of the Consolidated Edison Company of New York, Inc., and its affiliate, The Yonkers Electric Light and Power Company.

The failures selected for this presentation were chosen because their causes have been reasonably well-established, and the necessary corrective alterations have now been made to prevent recurrence. In some other instances it was difficult to determine the reasons for the thrust bearing failures, because of the almost total destruction which ensued. Without clues there is little chance of making an accurate appraisal of the factors contributing to the failure.

Still, it can be stated with some degree of certainty that, in our system, very rarely if ever, have the thrust bearing failures been the result of outright lubrication stoppage. Therefore, the failures that we have had on horizontal shaft units must be attributed to some temporary upset which boosted the thrust load to values several times higher than the calculated carrying capacity of the bearing, or else to the end result of gradual and slow wear of the thrusting surfaces.

Case 1

In horizontal auxiliary machines having little or no axial load, the thrust bearing consists of shaft shoulders, or equivalent arrangement, thrusting against parallel babbitted surfaces at each end of a journal bearing. This is a simple construction which is satisfactory in these cases because, in the absence of axial load, the function of the bearing is limited to the maintenance of the correct relationship between revolving and stationary elements.

Our systems have many auxiliaries provided with that type of thrust bearing and, in the main, they have given satisfactory service. There are, however, exceptions and among them the most outstanding are three identical General Electric turbines driving three 2,000 gallons per minute boiler feed pumps through reduction gears. These impulse turbines which revolve at 7,664 rpm are rated at 1,000 horsepower and transmit their power through Falk flexible couplings to reduction gear pinions so that no axial load is transmitted from the gears to the turbine shaft. All the bearings are forced lubricated by a shaft-driven gear oil pump which is part of the installation.

Since initial operations, some 25 years ago, the thrust bearings of these turbines have failed intermittently, sometimes in rapid succession and at other times taking several months of operation. After repeated investigations with negative results, efforts to reach a solution were abandoned and every one concerned arrived at the conclusion that these particular turbine thrust bearings were mechanical oddities.

This feeling had prevailed for a long time until recently when a new approach was initiated. The new study was precipitated by a series of thrust bearing failures which nearly crippled the Station.

As a first step in the new investigation, thermocouples were embedded in the thrust plate and their readings indicated metal temperatures as high as 190 degrees Fahrenheit. This was attributed to lubrication deficiency and the oil passages were enlarged so as to double the oil flow to the thrust bearing, but no improvement resulted. This led to the assumption that the axial thrust load was higher than computed and that a better type of thrust bearing was required to absorb it. Accordingly, the manufacturer advised us to substitute their standard tapered land thrust bearing plate for the old single plane stationary plate. Bearings of this newer type have their thrusting surfaces so designed that they can withstand loadings resulting in pressures of 175 to 250 pounds per square inch and are able for short intervals, to sustain pressures as high as 1,500 pounds per square inch with impunity. As this was several times greater than the load-carrying capacity of the old thrust bearing, it was hoped that there would be no need for increasing the thrusting surfaces, and this surface was kept to 11.77 square inches, as in the old type.

After the substitution, failures occurred again but it was observed that very often the temperature of the thrust plate was highest during starting operations. This observation led to the conclusion that damage originated during starting periods and that, once started, this damage progressed with more or less rapidity until total failure occurred. It was then decided to supply more oil during starting by introducing high pressure oil from the independent station system, and maintaining that pressure until the turbine had reached sufficient speed to insure hydrodynamic lubrication by the self-pumping effect in the thrust bearing.

As a result of these innovations, the life of the thrust bearing was extended,

Paper 50-270, recommended by the AIEE Power Generation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23-27, 1950. Manuscript submitted July 25, 1950; made available for printing September 19, 1950.

JOHN M. DRISCOLL is with the Consolidated Edison Company of New York, Inc., New York, N. Y., and H. C. OTTEN is with The Yonkers Electric Light and Power Company, Yonkers, N. Y.

Figure 1. Sketch illustrating changes in form and dimensions of thrust bearing elements to obtain satisfactory performance

but thermocouple temperatures gradually increased over a period of months to the point of failure of the bearing. It was then decided to increase the bearing surface from 11.77 square inches to 17.81 square inches, that is, by about 50 per cent. At the same time the oil piping was rearranged so that the turbine admission valves could not be opened unless the station central oil system was cut in and the thrust bearing supplied with high-pressure oil. Figure 1 shows the developed surfaces of the old and new thrust plates.

Since these last changes a few months ago, the thrust bearing metal temperature has not exceeded 140 degrees Fahrenheit which is the lowest temperature recorded for this bearing, and we now have confidence that the problem has finally been solved.

Case 2

No matter how disturbing to the operation of a power plant a thrust bearing failure of an auxiliary can be, it does not compare with the havoc which can be wrought by the loss of the thrust bearing of a turbine generator. For this reason, the balance of this paper will be devoted to failures of this latter type.

In the same station where the boiler feed pump mentioned previously is located, there is a General Electric 60,000 kw turbine generator which developed cracks in the high-pressure section of the turbine shell. At the appropriate time, it was decided to ship this turbine shell to the manufacturer for repair, and at the same time modernize the unit. Included in the alterations was the replacement of the turbine multicollar marine type thrust bearing by a tapered land thrust bearing.

After repairs and renovation the unit was tested, and the thrust bearing failed when full load was reached. Fortunately, the slender stub shaft carrying the thrust collar and overspeed governor vibrated so violently when the failure occurred that the overspeed governor operated and tripped the machine. Measurements taken afterwards indicated a turbine spindle shift of 0.140 inch toward the generator. As this was less than the smallest axial clearance, no internal damage resulted.

Upon inspection, the babbitted surface of the thrust ring was found to be completely wiped and the corresponding steel face of the thrust collar was badly scored for a width of about 2 inches near its outer rim. After rebabbitting the ring and grinding the collar, the thrust bearing was reassembled.

Hardly had the machine been restored to service when another thrust bearing failure developed. This time the machine did not trip itself but was tripped by the engineer hurriedly summoned, after smoke and oil temperature rise were first noticed. Less than one minute elapsed between the discovery of the trouble and the tripping of the machine. Measurements indicated a turbine spindle shift of 0.167 inch with serious damage to the packing strips.

A more detailed inspection of the component parts of the thrust bearing was made, and it was then found that the vertical wall of the thrust cage upon which the damaged thrust plate was bearing was relatively thin and was permanently dished out. After this finding, the cause for the failure became evident and was easily explained as follows:

Under the total thrust load, this wall of insufficient thickness deflected, and as the wall was receding from the thrust collar near the shaft, the load shifted radially and concentrated at the outer periphery of the thrust ring thus creating, at that location, enormous unit pressures and, ultimately, causing the failure of the ring and scoring of the thrust runner.

Temporary repairs were made, and pending receipt of a new, larger, and stronger thrust bearing, the machine was operated at a load which resulted in a thrust plate thermocouple temperature of 185 degrees Fahrenheit. In time the new thrust bearing was received and installed, and the load restriction was lifted. Figures 2 and 3 illustrate the preceding discussion.

The deflected position of the thrust plate as shown by the dotted line on Figure 2 is greatly exaggerated. Actually this deflection amounted to only a few mils but was nevertheless sufficiently large to cause the thrust bearing failure. And, although the thrusting surface which failed was enlarged in the new thrust bearing, the real cause was not in the faulty design of this surface proper but in an error in the structural computation of the thrust bearing cage.

Case 3

Of a different nature were the two thrust bearing failures which occurred in another unit. This other machine is a 50,000-kw tandem compound Westinghouse unit which had been in operation, at the time of the first failure, for 22 years. Besides this unit, we had two other identical ones, and when these machines misbehaved upon occasion, their Kingsbury thrust bearings were never involved.

Then one day, and for no apparent reason, the thrust bearing of this unit failed with severe damage to the blading. The thrust bearing destruction of course was complete and not much was left to establish the origin of the failure. However, during the inspection which followed it was found that a vent hole, which should have been provided at the top of the thrust cage did not exist. As no such omission was found in the two

other sister units, it was concluded that an air pocket had built up at the top of the thrust cage and had depressed the oil level in the cage to a point where parts of one or two top shoes did not bathe any longer in oil. The result of such a happening would be to overload the other shoes.

As mentioned earlier in this paper, complete certainty as to the causes of a failure is almost impossible to attain, and not everyone was in agreement with the above deduction, the main objection being one to which we could not find the answer, namely, why had this failure not occurred during the preceding 22 years.

The damaged rows of blades were cut out, the thrust collar was resurfaced, and the thrust shoes were rebabbitted. The unit was then restored to service, but with its maximum load limited to 30,000 kw because of the missing rows of blades.

The unit was operated under these conditions for about eight months without any further indication of thrust bearing trouble. It was finally taken out of service to reblade the high-pressure turbine and, at the same time modernize the whole unit. This work required approximately four months.

Shortly after the unit had been recommissioned, the thrust bearing failed again, and in the process many of the newly installed blades were either broken or so badly bent that they had to be renewed. Once more the thrust collar was resurfaced and the thrust shoes rebabbitted, but this time thermocouples were embedded in the thrust shoes on either side of the thrust collar, and as soon as the blading damage was repaired, some two months after the failure, the unit was returned to service.

To the general alarm of everyone concerned, it was found that the metal temperature of the loaded thrust shoes, as indicated by the thermocouples, was directly proportional to the kilowatt load and had already reached 185 degrees Fahrenheit when that load was only 40 megawatts, with every indication that the temperature would have continued to climb had the load been increased. Rather than risk a third failure, the load on the machine was limited to 40 megawatts and the problem referred to the manufacturer.

While awaiting the manufacturer's recommendations, the second identical unit in the station was taken out of service to install thermocouples in its thrust shoes for comparison purposes and it was found that under load their metal temperature was likewise running close to 180 degrees Fahrenheit. It was then assumed that these high temperatures must have prevailed during the past 23 years on both units.

Meanwhile, the manufacturer had reviewed the original data of these units and had found that the maximum axial thrust force was 63,300 pounds at 50,000 kw, resulting in a unit thrust shoe pressure of 443 pounds per square inch. In the opinion of the manufacturer this pressure was too high when compared with present-day design practice which limits the shoe loading of a Kingsbury type bearing to about 250 pounds per square inch, and he recommended that immediate steps be taken to unload the thrust bearing. This was carried out by the following method:

The 7-inch equilibrium pipe which connects the exhaust of the high-pressure turbine dummy was disconnected from the exhaust end of the high-pressure turbine and reconnected to the exhaust stage of the intermediate section of the low-pressure turbine. By this arrangement a greater pressure drop was attained across the dummy and the resultant thrust bearing loading was lowered. To control the pressure gradient across the dummy, an orifice and by-pass were placed on the equilibrium pipe.

With the by-pass, it also is possible to maintain the same exhaust dummy pressures whenever the dummy clearances change because of wear or damage of the dummy strips. Data covering desired pressures corresponding to definite loads were given to the station force, and it is

Figure 2. Inadequate stiffness of thrust bearing cage permitted slight deflection under load. Resulting local loading of thrust plate caused overheating and failure

Figure 3. Modified design of thrust bearing provided greater stiffness of cage wall and increased area of bearing surface

Figure 4 (above). Change in arrangement of piping introduced steam at lower pressures on low-pressure side of dummy. Axial thrust of dummy was thereby increased, leaving less load to be carried by thrust bearing

Figure 5 (right). Thick section of babbitt metal produced local expansion and consequent distortion of the running surface of the thrust plate. Nonuniform distribution of thrust load resulted and caused overheating of the metal

the duty of the operator to manipulate the by-pass valve to obtain these recommended dummy exhaust pressures as the load changes.

Figure 4 shows the piping alterations made to reduce the thrust load.

Case 4

From the experience derived from the cases previously reported, it is now the practice of the Consolidated Edison Company to install thermocouples in the metal of turbine generator thrust bearing plates or shoes. This job is done whenever the units are taken out in turn for overhaul, or in new units specified during contract negotiations.

Recently, one of these newly purchased units was commissioned with thermocouples installed in the thrust bearing plates by the manufacturer. However, our original request was for the thermocouples to be embedded in the steel section of the thrust plate as close to the root of the babbitt metal as possible without touching it. Instead, and because he considered such a method would not give true babbitt metal temperature, the manufacturer designed babbitt wells, or plugs, contiguous to the babbitt surface, as shown in Figure 5, which were intended to transmit the true babbitt metal temperature to the thermocouples without endangering the load surface of the babbitt by local pressure from the thermocouples.

After a few months of operation, the thermocouples began to show erratic readings and soon thereafter registered alarming high temperatures. As no corresponding increase in thrust bearing return oil temperatures was indicated, it was assumed that the recording instrument was at fault, but this was quickly dispelled by a test, and the machine was removed from service to inspect the thrust bearing.

At first no damage was noted but a closer observation showed two well-defined sections about 2 inches in diameter, slightly raised on the surface of one of the thrust plates. As they were in line with the two thermocouples embedded in the plate, it was immediately suspected that they were in some way responsible for the trouble. This led to an inquiry which revealed the existence of the construction related above.

In possession of this knowledge, an investigation was made of all possible causes which might force the babbitt plug to protrude, and the conclusion was drawn that the trouble was due to the difference in the thermal coefficient of expansion between steel and babbitt.

In Figure 5, the pertinent dimensions and results are given. They show that for an increase of 80 degrees Fahrenheit. above the shop temperature at which the plate was machined, the differential expansion of the plug was about 0.5 mil. As small as this dimension appears, it is a large percentage of the thickness of the oil film existing between runner and stationary plate, and the high temperatures indicated by the thermocouples reflected the local heating resulting from the extra load imposed upon the raised surfaces.

This type of construction now has been eliminated and the thermocouples are embedded in th thrust plates as originally specified.

Case 5

A 20,000-kw Curtis-type vertical shaft turbine generator was removed from one of the generating stations of the Consolidated Edison Company and was installed in 1947 in the Glenwood Station of The Yonkers Electric Light and Power Company. The machine was built in 1911 and was originally equipped with a thrust bearing of the step type requiring a continuous supply of oil at high pressure during operation. Because of the high cost of reconditioning and installing the large high-pressure pumps and accumulator, it was decided to equip the turbine generator at its new location with a Kingsbury thrust bearing. This decision was influenced by a record of some eight years of successful operation of a Kingsbury thrust bearing on a vertical shaft 15,000-kw Curtis turbine-generator at one of the stations of the Philadelphia Electric Company.

Operation of the 20,000-kw machine at the Glenwood Station in the city of

Yonkers, N. Y., commenced in December 1947, and no trouble of any kind was experienced during the first eleven months of operation of the Kingsbury thrust bearing.

In November 1948, a failure of the thrust bearing occurred while starting the machine. The trouble was indicated in two ways: first, more than the usual opening of the throttle was required to break away the turbine rotor. Second, the electric remote-indicating thermometer on the instrument panel showed an extremely rapid rise in temperature of the metal in one of the thrust bearing shoes as the shaft began to turn at slow speed. The throttle was immediately closed and the machine came to rest quickly without serious damage to the thrust bearing and without any damage to the turbine.

A very careful examination of the thrust bearing parts and a complete review of operating practices failed to reveal any cause for the failure. The lubricating oil supply had not been interrupted and the oil was exceptionally free of dirt and water.

The babbitt metal surfaces of the six pivoted segmental shoes of the thrust bearing were found to be undamaged except for scoring in a narrow band about $2^1/_2$-inches wide directly above the center of the pivot plug on the under side of each shoe. Looking down upon the assembled shoes the scored areas presented the shape of an annulus. The width of the babbitted surface of each shoe is about $9^1/_4$ inches in a radial direction.

The nickel alloy cast iron runner which is fastened to the bottom end of the vertical shaft of the machine and constitutes the upper element of the thrust bearing was also found to be discolored but not scored, in a ring-shaped area to match the scoring of the shoes.

Repairs were made by hand-stoning the under surface of the runner, in place, to remove visible particles of babbitt and a spare set of thrust shoes was installed.

Upon restoration to service, the thrust bearing operation appeared to be normal for four days. On the fifth day a groaning noise was noticed as the machine came to rest in shutting down. The noise was thought to come from the thrust bearing. The machine was started twice the next day and no abnormal temperatures of the thrust bearing shoe or of the oil were observed. The noise at shutdown persisted, however. At the next attempt to start the machine on the following day a rapid rise in indicated shoe temperature from 76 degrees Fahrenheit to 110 degrees Fahrenheit occurred and the machine was immediately shut down for inspection of the thrust bearing. Inspection showed that the shoes were scored in the same manner, but not as severely as before.

No specific cause for this failure could be found but the Kingsbury Company recommended the following changes:

1. That the lubricating oil be changed to an oil of higher viscosity, the change being from 140 Saybolt seconds universal to 220 Saybolt seconds universal at 100 degrees Fahrenheit.

2. That the babbitted surfaces of the thrust shoes be scraped to form a slight hollow of circular shape in the center of the shoe.

The successful operation of the bearing during the first eleven months after its installation was regarded as an indication that the over-all design of the bearing was adequate.

However, when the machine was operated after repairs were completed the groaning noise associated with the thrust bearing when the shaft came to standstill was present and was more severe than before. No unusual temperatures were observed but it was decided not to continue operation of the machine under these conditions. Accordingly the thrust bearing was once more opened for inspection.

No additional scoring was found but the babbitt metal showed many bright spots in the area outside of the central depressed area. It was the manufacturer's opinion that the louder noise which had been heard in shutting down could have been caused by the higher unit pressures resulting from the introduction of the hollow area in the center of each shoe. It was therefore decided to substitute a reconditioned set of shoes which had been scraped to a plane surface. The truth of the runner surface was checked with a straight edge and found satisfactory. The bearing was then reassembled.

Following the manufacturer's recommendation, the unit was started and stopped six times over a period of two days before being brought up to full speed and loaded. Regular operation continued for about two weeks during which the noise on shutdown persisted but no abnormal rise in temperature occurred until one day at the end of the period, when another failure was evidenced by a rapid rise in indicated temperature of the bearing shoe.

Upon the occurrence of this failure which was considered to be the fourth, it was decided to dismantle the entire thrust bearing and to return all of the parts to the factory for more thorough inspection and checks than were possible with the runner in place on the turbine shaft.

Inspection at the factory revealed two conditions which had not been found previously during field inspections conducted under difficult conditions. The cast-iron runner was found to have small particles

Figure 6. Simplified sketch showing the method used for introducing oil at high pressure to the active surfaces of a thrust bearing required to start and stop while subjected to heavy loading

of babbitt metal embedded in its surface. These were thought to be the result of the first failure of the bearing and the probable cause of the second, third and fourth failures. Hand-stoning would not remove the babbitt particles so the runner was reground and then lapped to a fine finish.

The runner surface also had been found to be very slightly convex instead of being in a true plane. When refinished the surface was left very slightly concave which was regarded as a more favorable condition.

It was the manufacturer's opinion at this stage of the investigation that the second, third and fourth failures might have been prevented had it been possible to observe the embedded particles of babbitt in the surface of the runner after the first failure.

It was decided at this time to make another change of lubricating oil to one of still higher viscosity, 415 Saybolt seconds universal at 100 degrees Fahrenheit, in an attempt to reduce metal-to-metal friction during the critical starting period. It was also decided to use the thrust shoes having a hollow depression in the center.

When the bearing was restored to service this time several months of successful operation were obtained but considerable apprehension was felt because of the continuance of the distinct groaning noise heard each time the unit was approaching standstill in shutting down. The noise occurred only while the shaft was making the last fraction of a turn to standstill. Over a period of several months this groaning noise was kept under close observation and seemed to be gradually becoming louder.

Another failure occurred in July 1949, this being the fifth failure. The manufacturer was then asked to consider design changes in the thrust bearing to make it adequate for the service required. The most obvious remedy, that of reducing the unit loading on the shoes, could not be applied since the load to be supported was fixed and the available space for the thrust bearing was limited by the existing dimensions of the turbine condenser and foundation.

Because of the fact that the bearing showed no sign of distress while operating at full speed it was decided to modify the design to provide for high-pressure forced lubrication of each of the pivoted shoes during starting and stopping periods only.

A method of applying high-pressure forced lubrication to the shoes of a Kingsbury type bearing was first employed in 1929 on two vertical shaft outdoor synchronous condensers of 25,000-kva rating at the Leaside Transformer Station in Toronto, Province of Ontario, Canada.[1] In that installation, high-pressure forced lubrication of the shoes was applied for the purpose of achieving a low-starting torque requirement.

Figure 6 is a simplified cross section of the Kingsbury thrust bearing applied to the 20,000-kw Curtis turbine at the Glenwood Generating Station. On the left side of the shaft center line is shown the original design of the bearing. On the right side of the center line is shown the method by which the high-pressure oil for supplementary lubrication was introduced at the center of the babbitted surface of each pivoted segmental shoe.

The modified thrust bearing was restored to service in October 1949, and has operated satisfactorily since that time. In the period from that date to June 30, 1950, there have been 169 starts of this turbine and 1,265 hours of operation.

It is our practice to start the high-pressure oil pump which has a capacity of 3 gallons per minute at 2,000 pounds per square inch gauge, at the same time that the low-pressure pump for normal lubrication of the turbine-generator is started.

The shaft of the turbine carrying a total weight of about 111 tons, lifts about $3^1/_2$ mils when the pressure at the face of the shoes is about 1,200 pounds per square inch gauge.

The turbine is then started and after full speed of 720 rpm is reached, the high-pressure oil pump is shut down.

When shutting down the main turbine the high-pressure oil pump is started when the turbine speed drops to about 100 rpm and is kept in operation until after the turbine shaft has come to a dead standstill.

It is believed that this procedure will result in continued satisfactory operation of the thrust bearing.

Conclusions

It should be made clear that, with one exception, the thrust bearing failures which are reported in this paper refer to old machines which were built when unit pressures adopted for thrust bearing design were nearly twice as large as the more conservative ones used today. Therefore, in new units trouble of this kind ought not to be encountered.

It has been our intention to show the important role played by the metal temperature-detecting-elements embedded in the thrust shoes or plates. With their help it has been possible to diagnose the trouble and follow the improvement resulting from successive alterations to thrust bearings. Also, as a temporary expedient, it has been possible to continue operation of important units at reduced loads by use of these devices as a guide.

These embedded temperature devices have been found capable of very fast response, and give indication of an abnormal temperature rise much more effectively than the conventional thermometer readings of the bearing oil return temperature. Under steady and normal conditions, the temperature differential between metal and oil was found to be 30 degrees Fahrenheit or more.

The favorable experience that we have had thus far with metal temperature-detecting-devices, has resulted in the decision of the Consolidated Edison Company to specify for new turbine generators on order, automatic alarm and tripping devices actuated by thermocouples embedded in the thrust bearing shoes or plates.

These devices now are expected to provide greater assurance of safety while permitting a minimum of attention from turbine room attendants.

Discussion

R. Sheppard (General Electric Company, Schenectady, N. Y.): There certainly can be no question that a thermocouple is one type of indicator that may be used to study progressive improvements in thrust bearing performance in steam turbines. When connected to a recording instrument, a permanent record may thus be kept. Increased temperature of the thrust plates gradually occurring over a period of time may indicate increased loading on the bearing due to formation of deposits upon the buckets or other abnormal change within the turbine.

Until about five years ago, it was the practice in thrust bearing design to combine the discharge oil flows from both the unloaded thrust plate and the loaded plate into a single drain line having one thermometer to register the outlet oil temperature. This practice originated in the old multirunner thrust bearings because it was difficult, if not impossible to separate the oil flows. With the development and introduction to steam turbine practice of the single collar

taper land bearings with two separate thrust plates, the old method of combining the outlet oil flows of the two plates was continued for many years. With a generous size oil supply line from the bearing oil header open right up to the oil grooves of the loaded and unloaded plates, the metered oil flow was regulated by the restriction of the 10 to 12 mils end clearance. The temperature of the combined outlet oil flows after mixing did not rise as a function of greatly increased thrust load.

It is well-known to all thrust bearing designers and experimenters that the power loss of a babbitted thrust plate increases rapidly as thrust load increases. The principal reason for the apparently negligible rise in oil temperature of a single collar thrust with combined discharges is explained in the next paragraph.

Division of oil flow through the two plates when there is no thrust on the bearing is approximately equal because the collar floats between the plates with about equal film thickness. As thrust increases in one direction, the film thickness decreases and somewhat less oil quantity will flow past this loaded plate. However, the clearance increases on the unloaded plate and a greater quantity of cool oil is drawn through it. The two oil streams combining on the discharge side thus exhibit only a negligible rise in temperature with wide changes in the thrust. It is, therefore, not surprising that operators gradually came to feel that the outlet oil temperature was a poor medium by which to judge thrust bearing performance.

Many of the thrust bearings in the turbine generator sets of the Consolidated Edison System have this combined discharge line with the single thermometer as described before. Thermocouples installed in the babbitted plates of these bearings are desirable, if there is any uncertainty, since a properly located thermocouple in the plate will indicate a much larger temperature change with wide variation in thrust load than would a thermocouple placed in the combined discharge oil line.

More recently, the single collar taper land thrust bearings for large turbine generators have all been designed with separate discharge oil passages with individual thermometers in the two oil flow lines. Figure 1 of this discussion represents actual observed temperature readings of the two thermometers as a function of turbine-generator load. The thrust in this particular turbine increased greatly with load and is in one direction throughout the load range. This arrangement of separated discharge oil flows very clearly indicates the direction of the

Figure 1. Temperature of oil leaving each side of a thrust bearing having separated oil discharges and thermometers

thrust in a unit, and the temperature rise of the loaded plate is appreciable and easily measured either with thermometers or with recording thermocouples. The outlet oil temperature varies as a function of the load on the turbine-generator through a wide enough range of temperatures that is practical to measure and to clearly indicate abnormal increases in turbine thrust.

The writer believes that the design of single collar thrust bearing with separately measurable oil discharge temperatures will permit satisfactory operator supervision of the turbine thrust bearing equal to that of a thermocouple inserted loosely in a hole in the steel thrust plate about 3/8 inch from the surface of the babbit.

Thrust bearings with embedded thermocouples in the thrust shoes or plates can be made on production units; however, to do so presents practical difficulties in threading them down through heavy bearing caps and housings in such a way that they can be removed easily when rolling out the heavy bearing parts during disassembly and inspections of the turbine. It would appear that a more rugged and lasting arrangement can be obtained if the thermocouples are permanently installed in the drain oil lines of the bearing pedestal where they do not have to be disturbed. They can be installed in the drain oil lines with much less complication to the manufacturers.

The authors make it clear in their conclusions that the thrust failures reported in this paper refer to older machines which were built with design margins far less conservative than present-day practice. This is certainly true considering the prevalence of thrust bearing failures 15 to 20 years ago. In this connection, it may be of interest to know that about 15 years ago the General Electric Company began a program of replacement of low margin thrust bearings in large units of older vintage. Hundreds of such modernizations have been accomplished so that today the industry is relatively free of disturbing thrust bearing failures.

It is the opinion of the writer that the adaptation of signaling and tripping devices that automatically shut down large essential prime movers upon indication of high thrust bearing temperature is justifiable only as a temporary measure on a particular machine whose thrust bearing is of marginal design, until such time as a stronger, more rugged thrust bearing can be installed.

An Air Delayed Selective Overcurrent Tripping Device for Low-Voltage Air Circuit Breakers

B. G. TREMBLAY
NONMEMBER AIEE

M. E. HORN
MEMBER AIEE

ECONOMICS of modern power distribution demand more than ever before that service on low-voltage systems be continuous and that unfaulted portions of the system receive a minimum of interference as a result of faults elsewhere on the system.

This requirement has popularized the use of selective tripping arrangement which, in turn, has imposed new requirements on both air circuit breakers and the tripping devices used with them. Because of the simplicity afforded by direct acting series tripping devices, attention has been focused on this type of device and its time-current characteristics.

The time-current requirement of a tripping device varies considerably with the position of the circuit breaker in a selective system and therefore a device providing a wide range of adjustment is essential for general application. To achieve the main objective, the device must function repeatedly as an accurate timer under variable temperature and atmospheric conditions, it must also possess the all-important feature of resetability which enables the device to respond to an overcurrent impulse but halt tripping action and automatically reset to its initial condition if the overcurrent condition is removed by some other protective device.

Paper 50-271, recommended by the AIEE Switchgear Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted June 29, 1950; made available for printing September 15, 1950.

B. G. Tremblay and M. E. Horn are both with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

A series device has been developed which provides a high degree of adjustability together with a delaying element which is virtually immune to temperature or other atmospheric changes for use with a new line of circuit breakers.

Design Features

This series overcurrent tripping device is air delayed with all of its elements completely adjustable. It is particularly well adapted for use in selective tripping systems. Such a device ready for mounting to a circuit breaker pole unit by means of two or four bolts, depending on coil rating, is shown in Figure 1. The unit shown has a 1,000-ampere coil rating. The maximum coil rating used with the 1,600-ampere frame size circuit breaker is 1,600 amperes. The same unit with the suitable coil can be used on the 225- and 600-ampere frame size circuit breakers.

The device consists of the two main subassemblies, namely:

1. The magnetic frame and coil assembly as shown in Figure 2(A).

2. The delay elements assembly as shown in Figure 2(B).

These two assemblies bolted together form the complete unit.

The magnetic frame and coil assembly, as can be seen from Figures 3, 4, 5, and 6, is always of the same construction and consists of the magnetic frame A, and the stationary core B around which is the series coil D. The magnetic circuit is completed by the moving core C which is part of the delay elements assembly.

The delay elements assembly contains the air chamber and the diaphragm as well as all of the elements to produce the adjustable long-time delay short-time delay, and instantaneous characteristics of the circuit breaker tripping curve. These three elements can be included singly or collectively in any combination.

All parts of these two subassemblies other than the magnetic circuit are made from nonferrous or noncorrosive materials. The diaphragm is molded integrally from silicone rubber and a synthetic fabric which has heat-resisting properties many times greater than that of cotton. A diaphragm made from these materials has been subjected to 4,000,000 operations at 175 degrees Fahrenheit over a period of four months, after which the diaphragm was still in good operating condition. The aging characteristics of silicone rubber are very good over a wide range of temperatures (approximately from −60 to 200 degrees centigrade.) Contrary to the behavior of natural or neoprene rubber, the tensile strength, hardness, and elongation of silicone rubber remain essentially constant with time over this wide range of temperatures.

An overload or short circuit current through the series coil D will cause the

Figure 1. Air delayed overcurrent tripping device with all its adjustable features

Figure 2. Air delayed overcurrent tripping device showing (A) the magnetic frame and coil assembly and (B) the delay elements assembly

moving core C to be attracted and move toward the stationary core B. At low currents, the moving core C will carry the tripping stem F along with it, immediately closing valve G, after which motion is retarded by the diaphragm E. The rate of travel of the diaphragm is determined by the rate at which air is permitted to enter chamber T by the various valves, H, J, and K. At higher currents when the attraction between the moving core C and the stationary core B is greater than the load on the spring inside the moving core, the moving core will compress the spring and travel independently of the tripping stem F. This spring ensures a constant maximum force pattern acting on diaphragm E. Up to the time the circuit breaker is tripped, this force must always be less than $A(p_a - p_t)$ where

A = area of diaphragm
p_a = atmospheric pressure
p_t = pressure inside air chamber T

By limiting in this way, the maximum force transmitted to the delaying element, the motion of the tripping plunger is dependent only on the rate at which air is admitted to chamber T through the long delay, short delay, and instantaneous valves.

Long-Time Delay Element

The long-time element purposely delays tripping of the breaker on motor starting, overload, and high impedance fault currents. As mentioned previously, Figure 3 shows how the tapered valve H controls the rate at which air is permitted to enter chamber T. For any given setting valve H remains fixed, but a wide variation of settings can be obtained by merely turning the long-time calibration dial S. The pickup current setting of the long delay element can be adjusted over a wide range by means of the adjusting screw P which controls the load on a spring. This spring, in turn, puts a restraining force on the moving core C through lever V.

Short-Time Delay Element

The short-time element intentionally delays tripping of the circuit breaker on fault currents. As in the long delay element, the short delay is controlled by the rate at which air is permitted to enter chamber T. Figure 4 shows how a second tapered valve J also working on the air chamber produces these short delays. Normally valve J is held closed by the adjustable spring Q through the armature M. On overcurrents, it is held closed by the pressure differential between the outside and inside of the air chamber in addition to the spring. The amount of delay is determined by the extent to which valve J is opened which in turn is controlled by the adjustable stop R. Since short delays are of the order of 4 to 30 cycles, this valve must therefore open a comparatively larger orifice than the valve controlling the long-time delay which produces delays of the order of seconds. The pickup current setting is determined when armature M is attracted to the magnetic frame A thereby opening valve J. This setting can be varied by means of the adjustable spring Q which loads the armature M and closes valve J in normal operation.

Figure 3. Schematic diagram of the long-time delay element

Figure 4. Schematic diagram of the short-time delay elements

Instantaneous Element

The instantaneous element provides no intentional delayed tripping of the circuit breaker, consequently, it is the fastest operating element. From Figure 5, it can be seen that its pickup is obtained by an armature L which is attracted to the magnetic frame A just as with the short-time pickup. The motion of this armature opens a valve K as wide and as fast

Figure 5. Schematic diagram of the instantaneous element

Figure 6. Schematic diagram of long-time delay, short-time delay, and instantaneous elements all on one unit

as possible so that the over-all circuit breaker clearing time may be as short as possible. The magnitude of current at which the pickup will take place can be varied by means of the adjustable spring N which also keeps the valve K closed during normal operation.

Finally in Figure 6, all of the elements that appear in Figures 3, 4, and 5 are combined into a single unit. The elements all perform their individual functions independently. Any or all of the three elements, namely the long delay, the short delay, and/or the instantaneous element may be made inoperative by replacing their easily accessible valves with a plug. In addition, the adjustable features of all the elements providing ranges of adjustment are still present. Reviewing again, these will give:

Calibration dial S—range of long-time delay.

Calibration knob P—range of long-time delay pickup.

Calibration knob R—range of short-time delay.

Calibration knob Q—range of short-time pickup

Calibration knob N—range of instantaneous pickup

Figure 7(A). Schematic diagram of a typical distribution system

Time Current Characteristics

The time-current curve of this air delayed device has an inverse time characteristic up to approximately 500 per cent of coil rating in the long-time range as seen in curve "A" of Figure 7(B). Within this range, the moving core and tripping stem move as a unit, that is, the magnetic pull has not increased sufficiently to overcome the loaded spring inside of the moving core. Above 500 per cent, the tripping time is constant with increase in current. Within this region, the magnetic force is sufficient to overcome the spring inside the moving core at the outset, thereby subjecting the diaphragm to the constant force pattern of the spring. The transition between the vertical and horizontal portions of the tripping curve have an inherently generous curvature due to the fact that the pickup points are obtained by overcoming spring loaded armatures. The effect of the pickup becomes noticeable toward the outer end of the time delay portion of the curve. In this region, the forces on the armatures as well as on the valve approach and pass through zero. And since this takes place in a finite time, it must reflect on the curvature at the transition point. Outside the transition region, the short-time delay also is constant for increasing currents.

It should be noted that the tripping characteristics are given as band curves, the top part of which represents the total clearing time. This is the duration of fault current flow, including arcing time. The lower limit of the band represents the resettable delay. This is the duration of fault current flow after which the circuit breaker may trip even though the fault current may subside to a value less than 80 per cent of the circuit breaker rating. However, if the fault current subsides in less than the resettable delay, the circuit breaker will not trip and the delaying device will reset. With this air delayed device, it is possible to maintain the band width at a minimum. Its complete ad-

Figure 9(A). Tripping characteristics of air delayed overcurrent tripping device showing range of pickup settings

justability eliminates the necessity of increasing the bandwidth to compensate for manufacturing variations and different coil ratings. The variation of tripping time due to temperature change has been almost completely eliminated from the bandwidth. This is possible with air as the delaying medium. The tripping time depends on the mean velocity with which the air flows through the orifice and it is not affected by changes in air density. It is, however, affected slightly by changes in viscosity. The viscosity of air varies approximately as the square root of the absolute temperature. This amounts to approximately 15 per cent variation for a 110 degrees Fahrenheit temperature change. Even this small change can be practically eliminated by the proper choice of valve materials, that is, a value that would increase the size of its orifice with an increase in temperature.

Range of Adjustment

The range of pickup settings for the long-time delay and the instantaneous elements are shown on Figure 8. The range of short-time delay pickup is shown on Figure 9(A). The range of long-time adjustment and the range of short-time adjustment are shown on Figure 9(B). These ranges are given quantitatively below:

Long-time pickup—from 80 to 160 per cent of coil rating.

Long-time delay—from 4 to 90 seconds (at 600 per cent of pickup).

Short-time pickup—from 500 to 1,000 per cent of coil rating.

Short-time delay—from 4 to 30 cycles.

Instantaneous pickup—from 1,000 to 1,500 per cent of coil rating.

Settings may be made at any value within these ranges by merely turning an adjusting knob as described previously in connection with the construction. The adjustments are independent of one another, that is, the long-time pickup can be changed without affecting the short-time pickup, or the long-time delay can be changed with a negligible change in the short-time delay. All of the possible combinations of adjustment and their effects on the tripping curve are illustrated in Figures 8 and 9.

Application of Air Displacement Device to a Selective System

Figure 7 shows the curves for a typical selectivity application together with a schematic diagram of the system. Curve "A" shows the characteristics for a 200 ampere-load circuit breaker *A* which is provided with long-time delay to permit motor starting and instantaneous tripping on currents above the motor starting range. Curve "B" shows the characteristics for a 350-ampere feeder circuit breaker *B* which is provided with long-time delay and short-time delay elements. The delay setting is such that a load fault at *X*, Figure 7(A), will be cleared by circuit breaker *A* while circuit breaker *B* remains closed and continues to feed

Figure 9(B). Tripping characteristics of air delayed overcurrent tripping device showing range of delay settings

Figure 10. Tripping characteristics of air delayed overcurrent tripping device with long-time and short-time elements

other load circuits. Curve "C" shows the characteristics for a 600-ampere sectionalizing circuit breaker *C* which also is provided with long-time delay and short-time delay elements. The delay setting in this case is longer than for circuit breaker *B* so that a feeder fault at point *Y*, Figure 7(A), will be cleared by circuit breaker *B*, thus permitting service on other feeders to continue uninterrupted. Curve "D" shows the characteristics for a 1,000-ampere transformer circuit breaker which is likewise provided with long-time delay and short-time delay elements. The short-time delay for any short circuit current is longer for circuit breaker *D* than for circuit breaker *C*. Assuming that only one of the transformers supplies the power at any given time (in this case transformer 1 supplies the power), then a bus fault at point *Z* will be cleared by the sectionalizing circuit breaker *C*. Circuit breaker *D* will remain closed and continue to feed power to bus number one without interruption.

Thus it can be seen that the relative short-time settings of circuit breakers *B*, *C*, and *D* provide the desired selectivity. These time bands must be compressed as closely as possible so that clearing time is not excessive in case of a bus fault. The upper limit of the maximum short-time delay band with this air delayed overcurrent tripping device is as low as 30 cycles as shown in Figure 10. Delay periods represented by the maximum, intermediate, and minimum short time bands shown in Figure 10 impose a severe thermal requirement on series coils of lower rating. Consequently, some limitation in application must be recognized. Table I shows the time bands to

Table I. Coil Ratings

Interrupting Rating in Rms Total Amperes	Range of Coil Rating—Amperes		
	Minimum Band	Intermediate Band	Maximum Band
15,000	100–225	125–225	150–225
25,000	175–600	200–600	250–600
50,000	350–1,600	400–1,600	500–1,600

which each coil is applicable. Coils having ratings less than those listed are applicable only where tripping is instantaneous for overcurrents above the motor starting range.

Conclusions

A series tripping device has been developed which provides all the basic delay characteristics required for either motor circuit protection or for use in selective tripping systems. By the use of filtered air as the escapement medium and by incorporating adjustable features to all pickup and delay settings, a tripping device has been provided which is both versatile in application and precise in operation over a wide range of operating temperature.

New Low-Voltage Air Circuit Breaker with 50,000 Ampere Interrupting Capacity at 600 Volts A-C

M. E. HORN
MEMBER AIEE

J. J. MIKOS
MEMBER AIEE

CONTINUED development during the last two decades has given to the art air circuit breakers of the low-voltage class with high interrupting capacities.[1] Arc chambers employing deionizing principles and arcing contacts made from metals instead of carbon have been major contributing factors in obtaining excellent performance in protecting distribution circuits.

The recent war saw these circuit breakers, with shock-proofing features added, protect main power and auxiliary power circuits in various military electric systems, particularly those on naval combat vessels.

The ability of low-voltage circuit breakers to meet extraordinary demands in performance during the war period, established the feasibility of raising the interrupting capacity and current carrying ability per-unit volume or unit mass of material used to produce the circuit breaker. The acceptable temperature rise measured at the terminal of a circuit breaker now has increased to 40 degrees centigrade. For enclosed circuit breakers the allowable rise is 55 degrees centigrade.

Many of the circuit breakers for naval use were equipped with series tripping arrangements which delayed the tripping to effect a measure of selective operation of circuit breakers on vital circuits. However, the circuit breaker contacts and closing arrangement had limited short-time rating which in turn greatly limited the range of fault current over which selective tripping could be offered.

The new low-voltage air circuit breaker discussed in this paper, offers not only a short-time rating equal to the interrupting rating, but includes an electrically operated closing means for closing and latching on this current. With these basic features, the new circuit breaker may be equipped with tripping devices of either the direct acting or relay type to provide full selective tripping performance over the complete range of fault current.

Principles of Design

Pole units on this circuit breaker have the current parts divided into a main current circuit and an arcing circuit. The main current carrying circuit consists of two upper bridging members on the moving contact arm and four lower bridging members associated with the upper terminal of the series coil as is indicated in Figure 1. This arrangement provides for making use of magnetic forces caused by short-circuit currents. By employing blow-on type of main contacts, it becomes possible to carry fault current for an appreciable length of time without excessive damage to the main contacts. As the lower bridges move away from the circuit breaker panel because of magnetic forces, the lower contacts of the upper bridges are subjected to this magnetic force causing the upper bridge to rotate against the upper stationary contact and exert pressure which tends to keep all the contact members tightly together during the period of high fault current. Contact springs need be only strong enough to provide the proper force per lineal inch of contact surface necessary to meet the allowable temperature rise. The upper main contacts are faced with a hard silver-nickel alloy to withstand the impact caused by electric closing and to maintain low contact drop.

The arcing circuit also is divided into two sections, namely, the secondary and primary contacts. Above the main contacts at the upper stud are the secondary contacts which also are constructed to be blow-on contacts. In the stationary portion of the arcing details is a flexible conductor which is so situated that when short-circuited current flows, the magnetic forces tend to increase pressure at the secondary contacts. This same flexible conductor has its loop placed in a manner to enhance the transfer of current from the path through the secondary contacts to the path through the primary or uppermost arcing contacts. An insulating barrier is provided between the secondary contacts and the upper main contacts to prevent hot gases generated by the arc at the primary arc tip from descending to the opening between the mains and causing a breakdown. A silver-tungsten alloy of such conductivity as to provide adequate protection for the main contacts when they are allowed to open, is placed on each secondary contact. The hardness of these secondary contacts must be sufficient to withstand considerable impact forces when closing the circuit breaker electrically.

Wide bearings at each moving contact arm hinge are provided to minimize any sidewise motion caused by interphase attractions and repulsions. Shunts around the moving contact arm hinge are provided to insure minimum friction in the hinges by the elimination of pitting. The primary arcing contacts are faced with a silver-tungsten alloy of lower conductivity and a greater hardness than the secondary contacts in order to withstand the impact caused by closing and latching against short-circuit currents and

Paper 50-272, recommended by the AIEE Switchgear Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted June 29, 1950; made available for printing September 15, 1950.

Figure 1 (above). Cross-sectional view of new low-voltage air circuit breaker in closed position

Figure 2 (below). Oscillogram of circuit calibration obtained by measuring the current through a bolted fault

to better withstand the erosion caused by arcing.

Extensive tests indicated that the contact materials selected perform better than any other known materials.

Arc extinction is obtained by employing the Deion principle[1,2,3] in an arc chamber consisting of steel plates[4] with V notches at the lower portion of the plate where the arc enters the arc chamber. These plates are interposed in the arc path at right angles to the arc. Above the steel plates are plates made from arc resisting insulating material to keep the arc confined in the arc chamber and to further cool the hot gases caused by the arc. The steel and the insulating plates are fitted into ceramic arcing shields in each side of the arc chamber.

The steel plates provide the necessary magnetic action to pull the arc into the chamber and against the plates causing the formation of a number of short arcs. Ionized gases give up great amounts of energy to the steel plates and to the ceramic shields which are so shaped that a throat is formed providing a Venturi effect to speed the gases upward. Proportions are such that the back pressure is kept to a minimum. Some turbulence is caused by the discontinuity between the steel and the insulating plates thus further cooling the exit gases.

Interruption tests were conducted on this circuit breaker, mounted in a cubicle which had a steel partition mounted $4^3/_8$ inches above the arc chambers and grounded to the circuit breaker frame and cubicle. Excellent interruptions were obtained with no failures.

The conventional insulating base was replaced with a strong steel framework on which individual pole units were mounted. Phase-to-ground insulation is provided by the base mold for the individual pole assemblies. By this arrangement, longer and more effective creep distances have been introduced which provide greater safety and conform to insulating standards associated with a maximum design alternating voltage of 625 volts.

The circuit breaker frame, vertical panel, and operating mechanism are all at ground potential, thus providing the greatest possible protection to personnel.

Figure 3 (right). Oscillogram of momentary test obtained by measuring the current through a closed circuit breaker. See Figure 2 for circuit calibration

Figure 4 (left). Oscillogram of opening test. Circuit breaker opened by energizing the shunt tripping device. See Figure 2 for circuit calibration

Figure 5 (right). Oscillogram of close-open test. Circuit breaker was tripped by series overcurrent device at the end of delay interval. See Figure 2 for circuit calibration

The operating mechanism for this circuit breaker is of the trip-free type designed for low mass and consequent high-speed tripping. Manual closing is provided for testing only. Molded insulating links on each pole unit provide the necessary dielectric between the operating mechanism and current carrying parts.

Low mass in the operating mechanism has been made possible by the use of fabricated stainless steel parts which have been heat treated. To insure long trouble-free life in this mechanism, corrosion-resistant metals have been employed.

A d-c closing solenoid has been chosen as the means for electrically operating this circuit breaker against short-circuit currents. High-speed closing is made possible with a simple device of small dimensions and weight. This solenoid is controlled by a relay designed for this particular duty. When the operating coil of the control relay is energized, a pair of contacts in series with the closing coil is closed by the movement of a magnetic core which is latched to an insulated arm containing the contacts. As soon as the relay contacts touch, the closing coil becomes energized and causes the moving core in the closing solenoid to latch the circuit breaker. Immediately after latching the breaker, the relay contacts are tripped free of the relay magnetic core by an arm mounted on the closing solenoid moving core. The closing coil current is interrupted by driving the arc into an arcing chamber by the aid of a blow-out coil in series with the relay contacts.

Attachments such as shunt trip, undervoltage trip with and without time delay, reverse current trip, alarm switch, auxiliary switch, key lock or key interlock, electric lockout, and operation counter do not change the over-all dimensions of the circuit breaker.

All attachments for the circuit breaker are self-contained subassemblies which may be mounted to the circuit breaker frame as required. These attachments may be readily added or changed in the field. Even the current rating of the circuit breaker may be changed in the field by replacing the series overcurrent tripping device with a replacement unit of the desired current rating.

The basic circuit breaker is free standing when unmounted. A removable or drawout circuit breaker unit is obtained by bolting to the basic circuit breaker the cell interlock, guiding rollers, lifting bar, and auxiliary contacts for control wiring and by adding contact finger assemblies to the circuit breaker terminals. No extra truck is required.

Employment of the basic design principles outlined in the foregoing has resulted in a degree of compactness never before realized as evidenced by Figures 6 and 7. The circuit breaker is 19.5-inches wide and is mounted three high in a 90-inch switchboard. The illustrations show the extension of a line of air circuit breakers which cover a current interrupting range of 15,000, 25,000, and 50,000 amperes.

Test Results

Many tests have been performed to establish the characteristics of this circuit breaker. Some of the results are recorded to illustrate the successful operation of the design principles employed in this circuit breaker.

Electric closing time measured from the time the control relay is energized to the time the circuit breaker is latched is seven cycles on a 60-cycle basis as shown in Figure 5.

Shunt tripping time measured from the time the shunt trip is energized to the time the circuit has been interrupted has been determined to be 3.4 cycles on a 60-cycle basis.

In line with existing practice of rating low-voltage air circuit breakers, Figure 2 illustrates an oscillogram of the circuit calibration with no circuit breaker in the circuit. An average of 55,400 amperes rms measured 1/2 cycle after the circuit was energized was obtained.

While closed, the circuit breaker was subjected to a short-circuit current for 33 cycles or 0.55 second. The average 3-phase current measured 1/2 cycle after the circuit was energized, was 49,530 amperes rms and was 36,600 amperes rms at the end of the 32nd cycle, Figure 3. No welding of contacts or appreciable deterioration of contacts was experienced in this test.

An oscillogram of an opening operation initiated by the shunt trip device is shown in Figure 4. An average 3-phase current of 53,000 amperes rms measured 1/2 cycle after the start of current flow through the circuit breaker was obtained. This opening operation was a clean interruption with a minimum amount of disturbance. Two minutes after the record shown in Figure 4 was taken, the oscillogram shown in Figure 5 was obtained. In this test the circuit breaker was electrically closed and latched against the short-circuit current which was allowed to flow through the circuit breaker for 24 cycles or 0.4 second. After this delay interval, the series overcurrent trip device tripped the circuit breaker and allowed the circuit breaker to interrupt the circuit. The circuit breaker closed and latched against 49,460 amperes rms measured 1/2 cycle after the start of current flow through the circuit breaker. At the 23rd cycle the average 3-phase current was 39,000 amperes rms.

These recorded results serve to indicate that the design principles discussed in this paper do make possible a circuit breaker which can close and latch against currents and have a 0.5-second rating equal to the interrupting rating of the air circuit breaker.

Conclusion

Through the employment of a unique contact arrangement and a highly discriminating use of space and material, a new low voltage circuit breaker has been provided which offers greater performance with a reduction in space and weight. The short time rating has been raised to equal the interrupting rating of 50,000 amperes.

The added ability to close and latch on this current permits tripping to be delayed throughout the entire range of fault current which, in turn, facilitates application to obtain the ultimate in selective tripping performance. A high degree of flexibility has been achieved in adapting the circuit breaker for drawout mounting and in adding or changing tripping devices or attachments in the field.

Discussion

Robert H. Nau (University of Illinois, Urbana, Ill.): The new low-voltage magnetic deion circuit breaker has certainly been perfected from the prototype of 1939.[1] Controlled engineering design has made this progress possible. Indeed, the unison of the mechanical and electrical features introduces a new acme for magnetic circuit breakers.

The several features are aptly described in the paper. The development and use of the molded insulation material for the base, the insulating links of the operating mechanism, and the arc chamber housings and internal barriers have done much in making possible the indicated compactness and the small unit mass. The new arrangement of main contact bridges utilizes the forces of current-loops to provide the necessary contact pressures and to eliminate contact chatter on short circuit.

The interrupting principles of the arc chamber have not been altered from the prototype. In the present paper, in the reiteration of the action of the arc chamber, it is stated that "the steel plates provide the necessary magnetic action to pull the arc into the chamber and against the plates, causing the formation of a number of short arcs." It does not seem that short arcs are truly formed. Such a transfer would mean a series of hot cathodes, which, in turn, would supply a terrific display of pyrotechnics at the currents of higher short circuits. Yet, it is known that no display is evident!

To be sure, I am indeed gratified to see that the mechanical development has been so completely extended from that which we had in 1938 and 1939.

1. See reference 5 of the paper.

M. E. Horn and J. J. Mikos: With reference to questions raised concerning the exact behavior of the arc inside the arc chamber during interruption the authors wish to direct attention to the following:

The slot shape in the magnetic splitter plates, shape of insulating shields, provisions for venting and so forth, are all arranged so that the arc is forcibly maneuvered into a position where arc voltage is substantially increased.

Therefore all of the mechanisms necessary for causing transfer into a number of shorter arcs are present. Conceivably transfer can take place at one place in the arc chute without a complete transfer throughout the entire length. Actually upon dissassembly of test samples the telltale marking produced by a cathode spot is present on some of the plates.

In conclusion, due to the relatively short arcing time required in a-c interruption, whether or not one or more additional cathode is formed, is of little significance as long as the required arc voltage is obtained.

Contributing Factors in Determining the Ratings of Power Transformers for Use on the Systems of The Hydro-Electric Power Commission of Ontario

D. B. FLEMING

J. S. LOTIMER
NONMEMBER AIEE

Synopsis: Transformers like most other commodities change in style from time to time as the years pass. It is the intent of this paper to delve back 40 years into the history of the Hydro-Electric Power Commission of Ontario and, in regard to transformers, compare the mode of thinking then with that of the present time, and to follow the changes that have occurred in four decades and the governing factors that have influenced these changes. Today a transformer can be considered to be one of the most reliable pieces of equipment in operation. It has been developed partially from operating experience and partially to satisfy conditions and circumstances that presented themselves. Tappings in a transformer can be extremely hazardous and therefore should be kept to a minimum. The indoor transformer has given place to the outdoor. Water cooling has been largely superseded by self-cooling, then forced-air cooling, finally augmented with forced-oil. Single-phase transformers once used exclusively are not now preferred to 3-phase units. Capacities have been stepped up from 750-kva to 100,000-kva units. Autotransformers are used to advantage whenever they can be applied. Both manually operated off-load and automatically controlled under-load tap changing equipment has been developed. Refinements have been made to temperature indicating devices. Current transformers used for relaying and control are now economically located on the bushings within the transformer tanks. Interchangeability of the various manufacturers' bushings has become a reality and is of great advantage to the operating companies. The gas detector relay is no longer an experiment but a sure telltale of trouble in transformers. The new features that have been added to transformers have appeared so gradually that unless one takes time out to compare notes they are not fully appreciated.

DURING its 40 years of operation the Hydro-Electric Power Commission of Ontario has purchased over 840 transformers for its 115,000- and 230,000-volt stations, totalling in capacity over 8,300,000-kva. The types and characteristics of the transformers purchased and installed have varied from time to time to best satisfy system conditions as they developed and to take advantage of new and improved features as they were introduced by the designers.

Over 98 per cent of the total kilovolt-ampere capacity of the transformers purchased are still in service, those disposed of being some of the original water-cooled indoor units.

1909–1920

The specification under which the Commission first purchased transformers for its 115,000-volt step-down stations called for:

750-, 1,250-, and 2,500-kva indoor transformers, 63,500/110,000Y—13,200-volts, 25 cycles, 40-degree-centigrade rise, 1-phase, water-cooled, with four $2^1/_2$ per cent under-voltage taps in the high-voltage and eight $2^1/_2$ per cent taps in the low-voltage winding (four above and four below normal voltage).

These transformers were installed in the ten original step-down stations strategically located in the more or less concentrated heavily industrialized centers of southern Ontario. In 1913 the section of the foregoing specification pertaining to the low-voltage windings was revised to provide for 26,400/13,200-volt windings on transformers to be installed in three additional stations which were then being constructed in areas where the load centers were widely distributed and from which long feeders would radiate.

With the limited experience at that time in the operation of 115,000-volt transformers, information was not available as to their reliability in the type of service contemplated. Accordingly, a spare unit was provided at each station. In the initial stages prospective load growth was rather uncertain and the possibility of having to install a second or replacement bank of larger unit capacity at the various stations, had to be kept in mind. Very few of the stations were conveniently located in respect to railway facilities, necessitating the skidding of the transformers from the railway sidings to station sites. With all the foregoing problems in mind single-phase transformers were considered to have an advantage over the heavier 3-phase units.

Forty years ago there were few, if any, 115,000-volt transformers of 750-kva capacity or larger, other than the water-cooled type. The water-cooled was cheaper than the self-cooled type and could be readily installed indoors on considerably less floor space, thereby greatly reducing the cost of installation, and avoiding station ventilating problems.

In the initial stages outdoor installations were not given very serious consideration by the Commission's engineers and not until 1921 was the first outdoor station erected at Hamilton.

Ratings of all transformers at this time were based on 40-degree-centigrade temperature rise with a 125 per cent capacity rating for two hours at 55 degrees centigrade. This method of rating was considered a reasonable attempt to provide the correct capacity in keeping with the daily load curve and was found to work out exceptionally well with water-cooled transformers. No great difficulty was experienced in keeping the ambient temperature within proper bounds. Cooling coils required little or no maintenance and

Paper 50-273, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 12, 1950; made available for printing September 18, 1950.

D. B. Fleming and J. S. Lotimer are both with The Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Canada.

the insulation was always in a healthy state.

The range of taps provided, in both the high-voltage and low-voltage windings, was considered necessary to take care of line regulation along the 115,000-volt transmission circuits from Niagara to Windsor, a distance of some 250 miles.

In 1916, fifteen 5,000-kva transformers were purchased to the same specifications to replace a group of 2,500-kva units, the former being the largest capacity transformers that could be accommodated in the original pockets. It may be of interest to note that all these 5,000-kva transformers are still in service at this location and no failures have occurred in their 34 years of operation.

1920–1930

In 1920 load growth on the system rapidly increased beyond the rated capacity of the installed transformers. Tests carried out on transformers in the manufacturers' plants at loadings simulating a normal daily load curve revealed that peak loads of over 140 per cent of rated capacity of the transformers could be carried without exceeding safe temperature limits. Increased loading of the existing transformers was authorized accordingly.

To provide for further load increase additional transformers were required. Consideration was given to outdoor installations. However, such installations did not appear to be warranted at stations where the existing indoor transformers could be replaced with larger capacity units. It was finally decided to purchase outdoor transformers and install them either indoor or outdoor as circumstances might dictate.

The specifications for new transformers called for:

Outdoor transformers, 63,500/110000Y—28,400/14,200-volts, 25 cycles, 55-degree-centigrade rise, 1-phase, water-cooled with two 5 per cent taps above and two 5 per cent taps below rated voltage in the high-voltage windings only.

The water-cooled type was retained with a view to keeping the size of the transformers within the existing pocket limitations. The rated capacity of these transformers was based on a temperature rise of 55 degrees centigrade to conform with the AIEE standard. However, as it was considered the existing cooling ponds might not altogether adequate, the transformers were to be rated 5,000-kva with 35-degree centigrade ambient. In order to keep within permissible temperature limits, the transformers had of necessity to be designed for larger capacity, their final rating being established at 6,000-kva.

Taps were eliminated from the low-voltage windings in view of the frequent mechanical failures experienced with many of the earlier transformers. These failures were considered directly attributable to the large range of taps with which the low-voltage windings had been equipped. In order to provide for the required range of tap positions, the taps on the high-voltage windings were increased to a range of 20 per cent, which unfortunately proved to be another weakness. The voltage rating of the low-voltage windings was raised sufficiently to compensate for regulation at full load 80 per cent power factor. Over 100 transformers normally rated 5,000 and 10,000-kva were purchased to the foregoing specifications.

In 1927 when considering equipment for the first 230,000-volt station to be erected at Leaside on a site immediately adjacent to the north-east boundary of the city of Toronto, it was decided to use water-cooled in preference to self-cooled transformers partially because of the restricted area of the site. Shortly after this station was placed in service, the load demand greatly exceeded the rated capacity of the transformers, necessitating their operation over long periods at hottest spot temperatures of 95 degrees centigrade. These 230,000-volt, and most of the foregoing 115,000-volt transformers were furnished with hottest-spot temperature indicating equipment and crude as it was, every effort was made to use it and operate the transformers on a temperature basis. It was soon realized that the cooling ponds were inadequate to take care of the extra losses resulting from this method of operation. Spray towers had to be erected, make-up water requirements were found to be excessive and the cooling coils also require frequent acid cleaning. As the result of this experience it was concluded that water-cooled transformers should not be used in future installations for other than generating stations where the water supply would be plentiful and pass through the cooling coils only once.

1930–1940

During the depression years of the 1930's very few transformers were purchased. However, those that were purchased were either self-cooled or forced-air-cooled. Forced-air cooling also was added to a number of the self-cooled units. Operation on a temperature basis was practiced to a greater degree and every effort was made to improve the temperature indicating equipment.

Just prior to the war, nearing the end of the depression period, the rapid load growth necessitated the formulation of a decided policy in regard to future transformers. Operating experience with the more modern transformers (those built subsequent to 1926) indicated that they were very reliable pieces of equipment. No failures were experienced on any of the 115,000-volt units. However, there were two failures on the 230,000-volt units, each of which was traceable to the inclusion of a 156,000-volt tap in the high-voltage winding. This tap was originally specified as a precautionary measure, should the 230,000-volt rating prove to be too high as an operating voltage. It reduced the impulse strength of the transformers, resulting in the failure of both of these units during heavy lightning storms. This tap was subsequently removed from all the transformers and no further electrical failures have occurred. No lightning arresters were in service at the time of the failures.

1940–1950

By 1939 confidence in the modern transformer had increased to such a degree that it was decided to install 3-phase transformers wherever possible. Specifications prepared for purchase of 115,000-volt transformers called for:

Outdoor transformers, 110,000-28,400/-14,200-volts, 25 cycles, 55-degree-centigrade rise, 3-phase, forced-air cooled, with four $2^1/_2$ per cent over-voltage taps in the high-voltage winding and equipped with hottest-spot temperature indicating equipment.

During the 10-year period 22 transformers of 25,000-kva capacity were purchased to this specification.

As long radial feeders emanating from a number of stepdown stations became heavily loaded, regulation became a serious problem. Accordingly, it was decided to erect small ancillary stations at strategic points to relieve this condition. At these stations, 8,000-kva transformers built to the foregoing specification and equipped with underload tap changers for automatic voltage regulation were used.

Modern station design makes no provision for the maintenance or rebuilding of transformers on the site. In all cases where major overhaul or repairs are required, it is the intent that the transformers will be returned either to the manufacturer's factory or to the Commission's central repair depot. A 135-ton depressed center car was procured for this

purpose to avoid the delay often experienced in obtaining suitable railway equipment. To provide for necessary spare capacity in the case of failure of an operating unit, provision is made for sufficient load transfer between adjacent stations to permit the removal and replacement of any unit that may become defective, the original practice of providing a spare unit at every station being discontinued.

In 1941 the Commission's second 230,000-volt station was brought into service at Burlington, located approximately five miles to the north of Hamilton. Transformers for the initial installation consisted of ten units (one spare) built to the following specifications:

25,000-kva outdoor transformers, 204,000 ground Y/118,000-68,250/118,000Y-13,200-volts, 25 cycles, 50-degree-centigrade rise, 1-phase, forced-air-cooled, with two 5 per cent taps in the high-voltage winding (one above and one below normal voltage).

The radiators were banked in A-frame structures, equipped with blowers and with conservator tanks mounted above, the cooling units being located to the rear of the transformers. The banked radiators greatly facilitate the installation of the units and simplify the separation of the transformer proper from its cooling equipment when removal is necessitated for maintenance or replacement purposes. The governing factor in determining the capacity of these transformers and the choice of 1-phase instead of 3-phase was the limitation in weights and dimensions that could be transported by rail.

Prior to the establishment of basic insulation levels by the AIEE, Edison Electric Institute, National Electrical Manufacturers Association Insulation Coordination Committee, the Commission's specifications called for insulation tests on all 115,000-volt transformers to be twice the highest tap voltage, that is, 242,000-volts. When insulation levels were established a choice had to be made between the 115,000- and 138,000-volt insulation classes. The choice was 115,000-volts for step-down transformers and 138,000-volts for generating-station transformers. It was felt that the higher factor of safety in the latter case was good insurance and the specifications were revised accordingly.

When forced-oil, forced-air cooling was first introduced by the manufacturers it was given very serious consideration by the Commission for installation on existing water-cooled transformers, the purpose being to eliminate cooling ponds, pumps and cooling coils, all of which were items of expense in the maintenance of water-cooled equipment. The transformers under consideration at the time however, were units of relatively small capacity and would each require one cooler only, necessitating the oil pump being in continuous operation while the transformer was in service. Accordingly, the failure of any one of three pumps would result in the loss of a complete transformer bank. This hazard was considered to rule out the contemplated replacements at single bank stations where means of load transfer was nonexistent. It also resulted in the deferment of the decision to use this equipment until some experience had been gained on the performance of the oil pumps.

In 1946 experimental tests were conducted on forced-oil forced-air cooling units in co-operation with one of the transformer manufacturers. These units were temporarily fitted to a 25,000-kva 3-phase transformer in operation at one of the Commission's stations. On completion of the experiments and final approval of the design by the manufacturer, the Commission purchased a number of 6,000-kva 1-phase transformers to be equipped with the new forced-oil forced-air coolers. These transformers were for installation in an extension to an existing station equipped with several banks of water-cooled units of similar capacity, where the pocket space and runway clearances had previously been established.

For service in stations with multiple transformer banks in operation, where the loss of any one bank would not be considered a hazard, due to the ready absorption of the rejected load by the banks remaining in service, the installation of unit coolers, one per transformer, was considered to be satisfactory, hence the purchase of the foregoing 6,000-kva units so equipped.

When considering the transformers for Kipling, the third 230,000-volt station, located immediately adjacent to the south-westerly limits of the city of Toronto, a bank of three transformers (plus one spare unit) was purchased to the same specifications as the Burlington transformers, with the exception that the new transformers were equipped with forced-oil forced-air coolers. By adopting this modification it was found possible to slightly lower the cost and appreciably reduce the space requirements.

Frequency Standardization

Frequency standardization introduced a new problem in the future purchase of transformers for the 25-cycle system. During the investigation stage it was considered expedient to provide for the efficient use of such equipment for either 25-or 60-cycle service, and require all transformers to be designed for dual frequency, that is, to be supplied for 25-cycle service with adequate provision made for ready reconnection for 60-cycle service in a minimum of outage time.

In regard to the existing installations it was decided that where the transformer reactance is relatively low, they would be operated at 60 cycles without any change in the windings. However, in the vast majority of cases, the transformers will have to be brought in for reconnection or replacement of a considerable portion of the windings. In the case of water-cooled transformers consideration will be given to the replacement of the cooling coils with forced-oil, forced-air cooling equipment.

A new 230,000-volt 60-cycle supply is being brought in to three of the Commission's latest step-down stations, namely: Kipling to the south-west of Toronto; Burlington to the north of Hamilton; and Westminster adjacent to London. Eight transformers are presently being installed at these stations: three at Kipling, two at Burlington and three at Westminster. All were purchased to the following specifications:

100,000-kva outdoor autotransformers, 228,800/116,900 ground Y-12,750-volts, 60 cycles, 55-degree-centigrade rise, 3-phase, forced-oil, forced-air cooled, with four taps in the high-voltage winding-223,300/217,850/212,650/207,450-volts.

When considering the transformers for these stations thought was first given to 2-winding 1-phase units, to provide a bank capacity equivalent to the capacity of the line. Network calculator studies however, showed that it was necessary to keep the reactance as low as possible in order to obtain a satisfactory margin of stability. Autotransformers appeared to be the answer to this problem. As they would materially reduce the physical size of the units required, 3-phase autotransformers were investigated. On advice from the manufacturers that 3-phase forced-oil forced-air cooled autotransformers of the capacity stated could be built and shipped and that no insurmountable problem existed in the design of such autotransformers, this type of unit was specified. The voltage ratings of these transformers appear as odd values. This is the result of trying for something different after the transformer design is well advanced and the coils are partially wound. Each 12,750-volt tertiary is associated with a 48,000-kva

13,800-volt hydrogen-cooled, synchronous condenser and permits over-excited operation without exceeding rated voltage on the condenser, thus reducing field heating.

In addition to the 100,000-kva autotransformers, four 60,000-kva autotransformers of similar voltage rating were purchased and are being installed at two line stations one adjacent to Peterborough and the other at Essa, adjacent to Barrie. It may be interesting to note that as a result of a subsequent change in plans, additional capacity for emergency use will be required in the 60,000-kva transformers and even though the designs were completed it was found possible to provide for the attachment to each transformer of two additional unit-type forced-oil forced-air coolers and thereby increase by 30 per cent, the rating of each transformer. These additional cooling units may be installed separately from the transformers and arranged to be automatically brought into service by thermal control on either one of the two transformers if the other becomes defective or is otherwise removed from service.

Conclusions

In the original 115,000-volt stations both high-voltage and low-voltage lightning arresters were used. Also in the first 230,000-volt station at Leaside lightning arresters were used for the protection of the first six banks of transformers. It is not now the Commission's standard practice to use lightning arresters at any high-voltage station and only a few of the older stations retain this equipment. However, all such stations are protected with overhead shielding and co-ordinating gaps. All the 115,000-volt transformers are fully insulated and only one electrical failure has occurred on any unit built since 1926. The Niagara 25-cycle system is operated with the high-voltage grounded at points through water resistors, approximating 250 ohms each. The other systems have solidly grounded neutral.

This paper would not be complete without mentioning the effort that has been made in Canada, for the past 25 years to bring about a certain measure of standardization of transformer bushings whereby those supplied by any one bushing manufacturer may be replaced by any other Canadian-made bushing of the same voltage rating. This is now in effect.

The efforts that the Commission has put forward in developing hottest-spot temperature indicating equipment that can be readily calibrated and maintained also has given results and such equipment is shortly to be placed in service.

For the protection of transformers, the Commission has experimented with the gas detector relay and has co-operated with the manufacturer in overcoming a number of short-comings in the original equipment.

The gas detector relay has never failed to operate in case of trouble in the transformers where installed.

The original transformers purchased were simple pieces of equipment in spite of their many taps, requiring large connecting boards, also the now obsolete chloride breathers. They were equipped with only the bare essentials for their operation. The transformers of today have many accessories, notably the large number of current transformers on all bushings. The 100,000-kva autotransformers previously referred to, each has a total of 26 current transformers mounted on the bushings inside the tank with all the secondary leads brought down to a common terminal box on the side of the case. Under-load tap changers, oil pumps, and blowers all require their controls with the interconnecting wires and conduit runs. Temperature equipment, oil conservators, relief vents, trucks and jack-steps, all make for a piece of equipment vastly different from the 1910 vintage, but each improvement was developed as conditions and circumstances demanded.

Discussion

D. W. Callander (Canadian Westinghouse Company, Limited, Hamilton, Ontario, Canada): Within the last 20 years many notable and important developments incorporated in the design of power transformers have greatly increased their reliability at the same time allowing for decreased weight and physical size per kilovolt-ampere in capacity output.

The intensive studies made in the late 1920's on lightning protection and insulation co-ordination have resulted in transformers with greatly improved impulse strength to withstand lightning and switching surges. In many instances the more economic arrangement of this improved insulation has resulted in reduction in the weight and the physical size of large high-voltage power transformers below those for transformers previously built for corresponding kilovolt-ampere capacities and voltages.

The use of the better grades of sheet steel recently made available (such as oriented cold rolled hipersil) has made possible transformers of reduced weight with improved magnetic performance.

In the manufacture of large power transformers, Westinghouse has always sponsored the use of the shell-type construction. Form-fit tanks now are standard for these transformers, their main advantages being further reduction in weight and physical dimensions, together with great reduction in oil content. This construction lends itself advantageously to the application of the various combinatjons of forced-oil and forced-air cooling. It also is advantageous in the application of transformers located at generating stations. Such transformers due to their comparatively small plan dimensions have made an appreciable saving in the concrete foundation required in the tail race of such power developments as Des Joachims and La Cave on the Ottawa River.

Altogether these developments involving reductions in weights and dimensions have allowed for the economic manufacture and ready shipments of transformers completely assembled (less accessories) of much larger ratings than were previously possible. It is interesting to note that the Hydro Electric Power Commission has always been in the forefront in taking full advantage of such developments in order to furnish economic and reliable service.

Stability of Servomechanisms with Linearly Varying Elements

M. J. KIRBY
MEMBER AIEE

As control technology progresses, more and more situations arise in which the variation of one or more elements with time cannot be ignored. The mass of a rocket decreases as its fuel is consumed. The inertia of a roll of strip steel in a mill changes as the steel is rolled or unrolled. In some cases, variation may be purposely introduced into the control system, for example so that a controlled process may proceed rapidly at first, then more slowly and smoothly during the final critical stages.

This paper presents a method for determining the stability of servosystems in which one or more elements vary linearly with time, that is, systems which can be described by a differential equation relating the output, θ_o, to the input, θ_i, and time, t, of the form

$$(a_n+b_nt)\frac{d^n\theta_o}{dt^n}+\ldots+(a_j+b_jt)\frac{d^j\theta_o}{dt^j}+\ldots+(a_0+b_0t)\theta_o=F(t) \quad (1)$$

The stability of such systems has sometimes been predicted by taking "snapshots" or sets of values of the coefficients at several discreet instants of time, and assuming that at each instant the system acts as a constant coefficient system having the appropriate coefficients. The present method is more rigorous since it is based on the actual solution rather than an assumed solution to equation 1. This solution is not always a simple exponential, as is shown for example by the case in which the damping remains constant but the inertia and gain vary. Furthermore, the method is simple to apply; determination of the absolute stability of a system described by equation 1 requires slightly less work than a single "snapshot" in the constant-coefficient-approximation method.

Equation 1 may be obtained, for example, by combining one equation relating motor torque to the error $(\theta_i-\theta_o)$ through the control network, with another equation relating motor torque to output, θ_o, through the load inertia, J, and damping, D. The right side, $F(t)$, is a known function of time, composed of θ_i, its derivatives, and products of these by t.

Stability is defined as Nyquist[1] defined it: a stable system is one in which an impressed small disturbance (which itself dies out) results in a response that dies out. More precisely, equation 1 is a linear equation; two or more solutions can be added and their sum will be a solution. Furthermore, the solution can be separated into a particular integral which is a function of $F(t)$ and is usually considered the steady-state solution, and a complimentary function dependent only upon the physical system and the energy stored in it initially. The complimentary function will be referred to henceforth as the transient response, and is the solution to equation 2,

$$(a_n+b_nt)\frac{d^n\theta_o}{dt^n}+\ldots+(a_j+b_jt)\frac{d^j\theta_o}{dt^j}+\ldots+(a_0+b_0t)\theta_o=0 \quad (2)$$

A system will be defined to be stable if the transient response, θ_o, when excited dies out completely as $t\rightarrow\infty$. If any part of the transient response persists or increases indefinitely, the system will be considered unstable.

The method of determining stability is based on the fact that the transient response can be expressed as a definite integral in the complex plane of an arbitrary complex variable herein called s. As $t\rightarrow\infty$, this integral approaches an exponential type of function in which the exponents are easily found from the rates of variation of the elements—the b coefficients in equation 1.

The Stability Criterion

It is not necessary to write this integral in order to apply the criterion. Stability is determined by the exponents, and a polar plot similar to a Nyquist plot is all that is needed. The specific steps in determining the stability of a system are:

1. Form the polynomial, $P(s)$ from the coefficients of the variable terms in equation 1, thus:

$$P(s)=b_ns^n+b_{n-1}s^{n-1}+\ldots+b_1s+b_0 \quad (3)$$

2. Plot $P(s)$ as s traverses a contour consisting of the imaginary axis from $-j\infty$ to $+j\infty$, and a semicircle of arbitrarily large radius, R, enclosing the right half plane. The plot will start from b_0 and will approach infinity at an angle of $+n\pi/2$ as s takes on purely imaginary values from zero to $+j\infty$. As s follows the semicircle of radius R, the b_n term overpowers all the others, and $P(s)$ follows a circular arc of radius b_nR^n from $+n\pi/2$ through zero to $-n\pi/2$. For purely imaginary values of s between zero and $-j\infty$, the plot of $P(s)$ is the reflection in the real axis of the plot for positive imaginary values of s.

Figure 1. Typical contour for equation 5 consisting of lines parallel to the real axis and small circles around the roots of P(s)

Paper 50-274, recommended by the AIEE Feedback Control Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted June 12, 1950; made available for printing September 11, 1950.

M. J. Kirby is with the Sperry Gyroscope Company, Great Neck, N. Y.

The writer wishes to acknowledge the assistance of Mrs. Ellen J. Adler, who planned and executed much of the electronic analogue computer work.

Figure 2. $P(s)$ is plotted as s traverses this contour, which encloses the right half (unstable region) of the s-plane. R is arbitrarily large

3. If the plot of $P(s)$ does not encircle the origins, the system is stable; if it encircles the origin, the system is unstable.

4. If the plot of $P(s)$ passes through the origin for finite, imaginary values of s, a type of response is indicated which has no counterpart in the performance of a constant coefficient system. The transient increases or decays as a power of t, which is slower than the familiar exponential rise or attenuation. In such a case, determine the numerical value of s for which $P(s)$ passes through the origin. For each such value, s_k, find the corresponding coefficient, λ_k, in the partial fractions expansion of $Q(s)/P(s)$ where $Q(s)$ is defined by equation 9 and

$$\lambda_k = \left.\frac{Q(s)}{\dfrac{dP(s)}{ds}}\right|_{s=s_k} \tag{4}$$

If the real part of each pertinent $(-\lambda_k-1)$ is negative, the system is stable. If any $(-\lambda_k-1)$ corresponding to a value of s_k for which $P(s)$ is zero, is positive, the system is unstable.

This method involves two restrictions. The elements of the servo must vary so that the coefficients of the differential equation describing the system have the form $(a+bt)$. This is often not too serious since practical variations can frequently be represented fairly well by a straight line throughout a reasonable time interval. A further restriction is that the coefficient of the highest order derivative term must vary; that is, b_n must exist. The remaining a subscript; and b subscript; coefficients may be either finite or zero.

The Transient Response Expressed as an Integral

The solution to equation 2 by means of definite integrals is discussed by a number of authors, including Forsyth,[2] Goursat,[3] and Ince.[4] The treatment given here follows Ince, chapter 18. It is pointed out there that the solution to equation 2 can be written as a contour integral

$$\theta_o(t) = \int e^{st} V(s) ds \tag{5}$$

Nomenclature

$a_1, a_2 \ldots a_j, a_n$ = constant parts of the coefficients of the differential equation describing the servo performance
$b_1, b_2 \ldots b_j, b_n$ = variable parts of the same coefficients
D = damping of servomotor and load
J = inertia of servomotor and load
$j = \sqrt{-1}$, also used as a subscript
J_0 = Bessel function, first kind, zero order
K = constant; in Figure 3 the gain of the servo
n = order of the differential equation describing the servo
$P(s)$ = polynomial in s defined by equation 6
$Q(s)$ = polynomial in s defined by equation 7
R = arbitrarily large radius in s-plane
r = arbitrarily small radius in s-plane
s = complex variable of integration
t = time
t_d = developed torque of servomotor
$V(s)$ = function of s, in contour integral expression for servo response
α_j = real part of γ_j
γ_n = j'th zero of $P(s)$
λ_1, λ_n = constant coefficients in the partial fractions expansion of $Q(s)/P(s)$
μ = complex constant, equation 10
θ_i = servo input
θ_o = servo output; usually denotes the transient part of the output
$\theta_1, \theta_r - \theta_j \theta_n$ = terms making up θ_o
ω_j = imaginary part of γ_j

when the function $V(s)$ and the contour C in the s-plane are properly chosen.

The conditions which $V(s)$ and C must satisfy can be determined by substituting the assumed solution (equation 5) into the equation 2.

$$\begin{aligned}(a_n+b_nt)\int_C s^n e^{st} V(s)ds + \ldots + \\ (a_j+b_jt)\int s^j e^{st} V(s)ds + \ldots + \\ (a_1+b_1t)\int_C se^{st} V(s)ds + \ldots + \\ (a_0+b_0t)\int_C e^{st} V(s)ds = 0\end{aligned} \tag{6}$$

Integration of the b terms by parts will remove t as a multiplying factor. When this is done, the equation becomes:

$$[(b_ns^n+\ldots+b_js^j+b_1s+b_0)e^{st}V(s)]_C + \int_C \left\{ \begin{aligned} &(a_ns^n+\ldots+a_js^j+\ldots+a_1s+a_0)V(s) \\ &\left[-\frac{d}{ds}(b_ds^n+\ldots+b_js^j+\ldots+b_1s+b_0)\right]V(s) \\ &-(b_ns^n+\ldots+b_js^j+\ldots+b_1s+b_0)\frac{dV(s)}{ds} \end{aligned} \right\} e^{st}ds = 0 \tag{7}$$

This will be satisfied if the contour C is chosen so that the term (in brackets) outside the integral sign is zero independent of t, and if $(V)s$ makes the differential expression inside the integral sign identically zero.

The function $V(s)$ must therefore satisfy the differential equation

$$P(s)\frac{dv}{ds} - Q(s)V = 0 \tag{8}$$

where

$$P(s) = b_ns^n+\ldots+b_js^j+\ldots+b_1s+b_0 \tag{3}$$

and

$$Q(s) = a_ns^n+\ldots+a_js^j+\ldots+a_1s+a_0 - [nb_ns^{n-1}+(n-1)b_{n-1}s^{n-2}+\ldots+2b_2s+b_1] \tag{9}$$

A useful form of the solution can be obtained by writing equation 8 as

$$\frac{1}{V}\frac{dv}{ds} = \mu + \frac{\lambda_1}{s-\gamma_1} + \frac{\lambda_2}{s-\gamma_2} + \ldots + \frac{\lambda_n}{s-\gamma_n} \tag{10}$$

where $\gamma_1, \gamma_2, \ldots \gamma_n$ are the zeros of $P(s)$ and the λ's are the constant coefficients in the partial fractions expansion of $Q(s)/P(s)$. μ is a constant which like $\lambda_1, \ldots, \lambda_n$ may be complex.

The solution is

$$V(s) = e^{\mu s}(s-\gamma_1)^{\lambda_1}(s-\gamma_2)^{\lambda_2}\ldots(s-\gamma_n)^{\lambda_n} \tag{11}$$

which has n singularities at the points $\gamma_1, \gamma_2, \ldots, \gamma_n$ in the s-plane.

It can be shown that a fundamental set of solutions to equation 2 can be obtained by using $V(s)$ given by equation 11, and a set of n contours, each of which follows a line parallel to the real axis and passing through a different one of the γ's, say γ_j. The representative point on each such contour starts at $-\infty$, moves along the line toward the particular γ_j until it is a small distance, r, from γ_j then encircles γ_j in the negative direction and retraces its linear path to $-\infty$. (See Figure 1).

This outline of the conditions which $V(s)$ and the contour C must satisfy is very sketchy. Further information and proofs are given in Chapters 5 and 8 in Ince.[4]

It might be noted in passing that equation 8 can be obtained formally by

Figure 3. Block diagram of second order servomechanism of Examples 1, 2, and 3

Figure 4 (left). Plot of $P(s)$ for Example 1. The plot starts and ends at $P(s)=1+j0$ and passes through the origin twice, for $s=\pm j$

Figure 6. Response of system of Example 2 to input of form $\theta_i=1/(0.1+t)$. The system equation is: $(1+0.4t)p^2\theta_o+(-1+0.5t)p\theta_o+(0.1+t)\theta_o=(0.1+t)\theta_i$

applying LaPlace transform techniques as explained, for example, by Churchill.[5] The present derivation, however, is especially adapted to the study of solutions to equation 2 which increase without limit as $t\rightarrow\infty$.

Form of the Transient as $t \rightarrow \infty$

Upon substituting expression 11 for $V(s)$, the integral becomes:

$$\theta_o=\int_c(s-\gamma_1)^{\lambda_1}(s-\gamma_2)^{\lambda_2}\ldots(s-\gamma_n)^{\lambda_n}e^{(s+1)t}ds \tag{12}$$

where the contour C, as shown in Figure 1, consists of three integrals, two along the line parallel to the real axis from $-\infty$ to (γ_j-r) and from (γ_j-r) to $-\infty$, and the third around the small circle of radius r with center at γ_j.

As $t\rightarrow\infty$, the first two integrals approach zero, and the third integral approaches the limit

$$\theta_j\rightarrow\frac{K_j e^{\gamma_j t}}{t^{\lambda+\lambda_j}} \tag{13}$$

where K_j is an arbitrary constant, and γ_j may have a real part α_j and an imaginary part ω_j.

The complete solution for θ_o therefore approaches the limit

$$\theta_o=\frac{K_1e^{\gamma_1 t}}{t^{\lambda+\lambda_1}}+\frac{\gamma^{\gamma t}}{t^{\lambda+\lambda_2}}+\ldots+\frac{K_ne^{\gamma_n t}}{t^{\lambda+\lambda_n}} \tag{14}$$

Equations 13 and 14 bring out the interesting fact that the transient response of a system described by equation 1 approaches a function in which the dominant part of each term is the exponential $e^{\alpha_j t}$ $(\cos\omega_j t+j\sin\omega_j t)$. Since the α's and ω's are the real and imaginary parts of the roots (γ's) of $P(s)$, the coefficients of the time-varying terms, $b_n\ldots b_0$, in equation 2 determine whether or not the solution is oscillatory, the frequency if it is oscillatory, and the damping. In so doing, the b's play much the same role as do the coefficients in the characteristic equation corresponding to a differential equation with constant coefficients.

Each exponential function is multiplied by $t^{-\lambda_j-1}$, but this is overpowered by $e^{\alpha_j t}$ whenever α_j is not zero. Thus the eventual rate of rise or decay of the transient, the stability of the system, is determined by the coefficients of the time-varying terms; if all the α's are negative the system is stable, if any α is positive the system is unstable.

If no α is positive, but one or more are zero, the $1/t^{\lambda+1}$ factors for these terms will determine the system stability. The transient response is oscillatory with frequency ω_j but rises or decays as $1/t^{\lambda+1}$ which will frequently be a fractional power of t. The response has no counterpart of the performance of constant coefficient system; the increase or decay of the transient is much slower than the familiar exponential rise or decay. Bessel functions of zero order are functions of this type (see the first example which follows).

The problem of determining stability now is reduced to the problem of investigating the location, in the s-plane, of the γ's which are the roots of $P(s)$. There are three possible cases:

1. If all the γ's lie in the left half of the s-plane, the system is stable.

2. If any γ lies in the right half of the s-plane, the system is unstable.

3. If any γ lies in the imaginary axis of the s-plane, the stability of the system must be determined from the $t^{-\lambda-1}$ factor for each such term. If each pertinent $(-\lambda-1)$ is negative, the system is stable. If any $(-\lambda-1)$, corresponding to a γ lying on the axis, is positive, the system is unstable.

A convenient means of determining how many γ's lie on the imaginary axis or in the right half of the s-plane is to plot the function $P(s)$ as the representative point describes a contour which encloses the right half of the s-plane. A theorem (see Copson,[6] or James, Nichols, and Phillips,[7]) sometimes referred to as "The Principle of the Argument" states that as the representative point traverses the contour once the plot of the function $P(s)$ will encircle the origin once in the positive direction for each γ which lies inside the contour, that is, in the right half or unstable region of the s-plane.

The contour used here consists of the imaginary axis from $s=-j\infty$ to $+j\infty$, together with a semicircle whose radius

Figure 5. Plot of $P(s)$ for Example 2. No encirclement of origin; system is unstable

Figure 7. Plot of $(P)s$ for Example 3. Two encirclements of origin; system is unstable

Figure 8. Response of system of Example 3 to input of form $\theta_i = 1/(1+t)$. The system equation is: $(1+0.4t)p^2\theta_o + (1-0.1t)p\theta_o + (1+t)\theta_o = (1+t)\theta_i$

approaches infinity, enclosing the right half plane, (Figure 2).

The plot of $P(s)$ begins at b_0 for $s=0$, and approaches infinity as $s \to +j\infty$; the angle of $P(s)$ approaches $\doteq \pi/2$ if the highest power of s in $P(s)$ is unity, $\doteq \pi$ if the highest power is s^2, and in general $\doteq n\pi/2$ where $P(s)$ is of the order n.

In order to avoid confusion as to the number of encirclements, $P(s)$ should be plotted for values of s on the semicircular part of the contour as well as along the imaginary axis. This can be easily accomplished by letting the radius of the semicircle be an arbitrary value, R, large enough so that all possible roots of $P(s)$ are inside the semicircle, and large enough so that all terms of $P(s)$ except $b_n s^n$ can be neglected. As the representative point in the s-plane travels clockwise around the semicircle from $s=+jR$ to $s=-jR$, the plot of $P(s)$ follows a circular arc of radius $b_n R^n$ from $+n\pi/2$ through zero to $-n\pi/2$. Figures 4, 5, 7, and 9 illustrate this.

The labor of plotting $P(s)$ is lessened by the fact that for pure imaginary values of s the real part of $P(s)$ is an even function and the imaginary part of $P(s)$ is an odd function. The plot of $P(s)$ for negative imaginary values of s is the reflection in the real axis of the plot for positive imaginary values of s.

If any of the γ's have zero real parts, the plot of $P(s)$ will pass through the origin of the $P(s)$ plane for the corresponding finite imaginary values of s. This is case 3 mentioned previously, and the following procedure (see, for example, Churchill[9]), can be used to determine whether $(-\lambda-1)$ is positive or negative for each lying on the imaginary axis.

Find the numerical value of s at which the zero of $P(s)$ occurs. This is the value of s for which the plot of $P(s)$ passes through the origin. Call this s_k. The value of λ_k, the coefficient of the $1/s-s_k$ term in the partial fractions expansion of $Q(s)/P(s)$ is

$$\lambda_k = \left.\frac{Q(s)}{\dfrac{dP(s)}{ds}}\right|_{s=s_k} \tag{4}$$

where $Q(s)$ is defined by equation 9.

It is not necessary, of course, to find the value of λ corresponding to any γ which has a nonzero real part.

It might be noted that the stability criterion could be stated in terms of a plot of $1/P(s)$ as well as $P(s)$. A plot of $1/P(s)$ would start at $1/b_0$ and approach the origin, describing a small circular arc of radius $1/b_n R^n$ as s follows the semicircle. Encirclement of the origin would determine stability, in a manner similar to the present criterion. If any of the zeros of $P(s)$ lie on the imaginary axis, the plot of $1/P(s)$ would be infinite for the corresponding values of s.

The stability criterion can be modified and extended to apply to servomechanisms in which the elements vary as powers of t higher than the first. Space does not permit this in the present paper, but will be the subject of a future paper.

Examples

In the interest of brevity, the number of examples which follow is held to the minimum. The plots of the response to typical test inputs, θ_i, which are included in examples 2 to 4 were obtained with the aid of an electronic analogue computer. The number of computing elements available limited the examples to second and third order systems. The amount of noise inherent in certain of the elements

Figure 10. Response of system of Example 4 to an input of form $\theta_i = 1/(1+0.4t)$. The system equation is: $(1+0.4t)p^3\theta_o + (1+0.3t)p^2\theta_o + (1+0.4t)p\theta_o + (1+0.4t)\theta_o = (1+0.4t)\theta_i$

limited the gains which could be used, particularly the variable part of the coefficient of the highest order derivative. These limitations are not serious, but explain what may appear to be arbitrary choices of the numerical values of a_0, b_2, a_3, b_3, and so forth.

Example 1

In order to provide a familiar starting point, this example concerns a system whose transient response is a Bessel Function of order zero.

Consider a servo consisting of a motor driving an inertia load with viscous damping. The amount of damping does not vary, but the inertia J and the gain, K, increase linearly with time, and are so small as to be negligible at $t=0$, Figure 3. For convenience assume the numerical values of the fixed damping and the rates of increase of inertia and gain are all unity.

The differential equation for the system is

$$t\frac{d^2\theta_o}{dt^2} + \frac{d\theta_o}{dt} + t\theta_o = t\theta_i \tag{15}$$

since

$$b_2 = 1,\ b_1 = 0,\ b_0 = 1$$
$$P(s) = s^2 + 1 \tag{16}$$

The plot of $P(s)$, Figure 4, shows poles on the imaginary axis, at $s=\pm j$; the stability must be determined from the values of λ associated with the $1/(s+j)$

Figure 9. Plot of P(s) for Example 4. Two encirclements of the origin; the system is unstable

Figure 11. Comparison of polar plots for four third-order systems having the system equations shown. To compare plots, adjust scales so that all start from the same point at $\omega=0$. Thus, plot A is actually farthest from the origin

Figure 12. Location of zeros of $P(s)$ for the four systems of Figure 11

term in the partial-fraction expansion of $Q(s)/P(s)$

$$\lambda = \left.\frac{Q(s)}{\dfrac{dP(s)}{ds}}\right|_{s=j} \tag{4}$$

where

$$Q(s) = -s \qquad \frac{dP}{ds} = 2s$$

$$\lambda_j = -\frac{1}{2} \qquad -\lambda_j - 1 = -\frac{1}{2}$$

This indicates that the transient response of the servo approaches $(1/\sqrt{t})\cdot(e^{jt}+e^{-jt})$ times a suitable constant; hence is stable, although it approaches zero quite slowly as $t \to \infty$.

The stability of this servo can be verified analytically, since its transient response is a tabulated function. If θ_i is a unit step, for example, and $\theta_o = 0$ initially, the solution to equation 16 is

$$\theta_o = 1 - J_0(t) \tag{17}$$

The transient, $J_0(t)$ approaches zero as $t \to \infty$; furthermore, at large values of t,

$$J_0(t) \to \frac{K \cos t - \frac{\pi}{4}}{\sqrt{t}} \tag{18}$$

where K is a constant (see, for example, McLachlan[9]). McLachlan[10] discusses the derivation of asymptotic expansions for Bessel function using contour integrals wherein the contours consist of lines parallel to the real axis, and encirclements of singular points, similar to Figure 1.

Example 2

Consider a second-order servo like that of Figure 1, but in which the inertia and gain are not zero initially. Assume that the damping is initially negative but increases with time, so that the differential equation is

$$(1+0.4t)\frac{d^2\theta_o}{dt^2} + (-1+0.5t)\frac{d\theta_o}{dt} + (0.1+t)\theta_o = (0.1+t)\theta_i \tag{19}$$

If stability depended on the constant coefficients a_2, a_1, a_0, the system would be violently unstable because of the negative damping, a_1. However, for this system

$$P(s) = 0.4s^2 + 0.5s + 1 \tag{20}$$

and the plot of $P(s)$, Figure 5, indicates stability because there is no encirclement of the origin.

Figure 6 is a plot of the response of this system to an input of the form

$$\theta_i = \frac{1}{0.1+t} \tag{21}$$

and shows that the servo is indeed stable. Its transient decays more rapidly than that of the previous example, because of the presence of the damping term, b_1, in $P(s)$.

Example 3

A servo similar to the previous one but in which the damping is initially large and positive and changes slowly in the negative direction is considered next. Assume the numerical values are such as to give the differential equation:

$$(1+0.4t)\frac{d^2\theta_o}{dt^2} + (1-0.1t)\frac{d\theta_o}{dt} + (1+t)\theta_o = (1+t)\theta_i \tag{22}$$

Figure 7 is a plot of $P(s)$, which is:

$$P(s) = 0.4s^2 - 0.1s + 1 \tag{23}$$

This encircles the origin, indicating instability. The response of the servo to the input

$$\theta_i = \frac{1}{1+t} \tag{24}$$

is given in Figure 8 and verifies the instability. (The solution was not continued for a longer time because of overloading of some of the elements of the computer). If the constant coefficients, a_2, a_1, a_0 alone were effective in determining stability, the system would be stable, whereas it is actually unstable owing to the negative value of b_1. Increasing the amount of positive constant damping, a_1, would postpone but never eliminate the eventual instability of this system.

Example 4

Assume that in some manner a servo has been obtained which is described by

Figure 13(A). Response of system *A*, Figure 11, to input $\theta_i = 40/(1+0.2t)$. The system equation is: $(1+0.2t)p^2\theta_o + (0.5+t)p^2\theta_o + (0.5+t)p\theta_o + (1+0.2t)\theta_o = (1+0.2t)\theta_i$. Broken line is approximate steady-state response

Figure 13(B). Response of system *B*, Figure 11, to input $\theta_i = 40/(1+0.4t)$. The system equation is: $(1+0.4t)p^2\theta_o + (1+t)p^2\theta_o + (1+t)p\theta_o + (1+0.4t)\theta_o = (1+0.4t)\theta_i$

Figure 13(C). Response of system C, Figure 11, to input $\theta_i=40/(1+0.4t)$. The system equation is: $(1+0.4t)p^3\theta_o+(0.5+0.1t)p^2\theta_o+(0.5+t)p\theta_o+(1+0.4t)\theta_o=(1+0.4t)\theta_i$. Broken line is approximate steady-state response

Figure 13(D). Response of system D, Figure 11, to an input $\theta_i=40/(1+0.4t)$. The system equation is: $(1+0.4t)p^3\theta_o+(1+0.8t)p^2\theta_o+(1+0.4t)p\theta_o+(1+0.4t)\theta_o=(1+0.4t)\theta_i$. Broken line is approximate steady-state response

the differential equation:

$$(1+0.4t)\frac{d^3\theta_o}{dt^3}+(1+0.3t)\frac{d^2\theta_o}{dt^2}+(1+0.4t)\frac{d\theta_o}{dt}+(1+0.4t)\theta_o=(1+0.4t)\theta_i \quad (25)$$

The function $P(s)$ is plotted in Figure 9.

$$P(s)=0.4s^3+0.3s^2+0.4s+0.4 \quad (26)$$

and indicates instability by encircling the origin, Figure 13, which is the response to an input:

$$\theta_i=\frac{1}{1+0.4t} \quad (27)$$

illustrates the instability.

Relative Stability

A polar plot of $P(s)$, in addition to indicating absolute stability, gives information about the form of the servo response at large values of time. Since the main parts of the terms in the response are exponentials whose exponents are the zeros of $P(s)$, the locations of these zeros in the complex s-plane determine the response. The distance of each zero from the real axis determines the frequency of oscillation; the distance from the imaginary axis determines the rapidity of damping; the farther from the real axis, the higher the frequency of oscillation; the closer to the imaginary axis, the longer the "tail", the slower the decay.

The closeness with which the polar plot approaches the critical point in the $P(s)$ plane indicates the closeness of the zeros to the imaginary axis in the s-plane. The frequency (ω) at which the polar plot most closely approaches the critical point is the predominant frequency of the oscillation.

These properties of the polar plot are illustrated by Figures 11, 12, and 13. Figure 11 contains polar plots of four third-order systems, Figure 12 shows the locations of the zeros of $P(s)$ in the s-plane for these servomechanisms, and Figure 13 displays their responses to an input of the form $\theta_i=1/(1+t)$. In order to correctly compare the closeness of the polar plots to the origin of the $P(s)$ plane, their respective scales must be adjusted so that all plots start from the same point at zero frequency. When this is done, it can be seen that as the polar plots approach progressively closer to the origin, the transient response decays more slowly. (The decaying steady state response, which is approximately $1/(1+t)$, should not be confused with the transient.)

It must be remembered that $P(s)$ is not a "transfer function" but rather has the properties of a characteristic equation. While a plot of $P(s)$ can indicate the frequency and relative damping of the terms in the transient response, it cannot indicate the magnitudes of the terms, hence cannot indicate overshoot.

Discussion

G. M. Anderson and **William Caywood, Jr.** (Carnegie Institute of Technology, Pittsburgh, Pa.): Dr. Kirby is to be congratulated for an elegant treatment of the stability problem of servomechanisms defined by a differential equation with linearly time varying coefficients. The analysis extends the usual stability criterion applicable to linear differential equations with constant coefficients in a logical, simple manner.

It is felt that perhaps some emphasis should be placed on the result that there is one simple condition, which can be determined by inspection, which is an indication of instability. As is suspected by analogy with the constant coefficient system all of the b coefficients must be of the same algebraic sign, otherwise there are zeros of $P(s)$ to the right of the imaginary axis and the system cannot be stable. Mere fulfillment of this condition is not sufficient in itself to insure stability but it is necessary.

There is another simple requirement for stability that is applicable to systems with constant coefficients, that all of the lower order terms must exist. The analogous conclusion can not be so simply drawn with the $P(s)$ function as missing terms also may be due to zeros on the imaginary axis, resulting in a critical case as is discussed in the paper.

The following errors were noted in the text. The character μ as defined by equation 10 is a real number since $\mu=a_n/b_n$. It is not complex as claimed.

Stability condition (3) following equation 14 should be corrected, in part, to read: ...If "the real part of" each pertinent $(-\lambda-1)$ is negative, the system is stable. If "the real part of" any $(-\lambda-1)$, corresponding to a γ lying on the axis is positive the system is unstable.

The reason for the insertion of "the real part of" is that λ will in general be complex. Consider the system defined by

$$t\frac{d^2\theta_o}{dt^2}+\frac{d\theta_o}{dt}+(1+t)\theta_o=0$$

which is identical with Example 1 given in the paper, except for the addition of $a_0=1$. In this case

$$P(s)=s^2+1$$
$$Q(s)=s+1-[2s]=1-s$$
$$\lambda_j=\left.\frac{Q(s)}{\frac{dP}{ds}}\right|_{s=j}=\left.\frac{1-s}{2s}\right|_{s=j}=\frac{-1}{2}[1+j]$$

and

$$-\lambda_j-1=-\frac{1}{2}[1-j]$$

L. A. Zadeh (Columbia University, New York, N. Y.): This paper is a welcome contribution to the theory of stability of variable systems. The stability criterion developed by M. J. Kirby is essentially a criterion for the so-called asymptotic stability of a system. Under this criterion, a system is stable if the transient response or, more precisely, any solution of equation 7 of the paper, dies out as $t \to \infty$. Thus, on the basis of this criterion a system whose response to an input exhibits violent overshoots over the period of observation, but is such that the response eventually dies out as $t \to \infty$, would be classified as a stable system. It is evident, however, that in most practical cases it would not be justifiable to classify a system as stable or unstable solely on the basis of the behavior of the system for very large t, particularly since this phase of the behavior is frequently of little practical interest. The fact that the author's criterion does not provide any information whatsoever regarding the magnitude of the overshoots, constitutes in my opinion a serious shortcoming of this criterion.

It should be noted that in general it is easiest to investigate the location of the zeros of $P(s)$ by using Hurwitz's criterion,[1] which eliminates the necessity for plotting $P(s)$. In particular, in Example 3, the instability of the system follows immediately from the fact that one of the coefficients in $P(s)$ is negative. Any polynomial having one or more negative coefficients is certain to have some zeros in the right half of the s-plane.

For the case where none of the coefficients b_j is zero, Mr. Kirby's criterion can readily be obtained by noting that for large values of t the terms a_j become negligible versus $b_j t$ and hence the differential equation becomes

$$b_n t \frac{d^n \theta_0}{dt^n} + \ldots + b_1 t \frac{d\theta_0}{dt} + b_0 \theta_0 = 0 \qquad (1)$$

or

$$b_n \frac{d^n \theta_0}{dt^n} + \ldots + b_1 \frac{d\theta_0}{dt} + b_0 \theta_0 = 0 \qquad (2)$$

This constant-coefficient equation describes the asymptotic behavior of θ_0 and hence the condition for asymptotic stability is that the characteristic roots of this equation should have negative real parts. This is essentially the criterion given by the author.

The above derivation fails when some of the b_j's are zero. For this case it is necessary to use the rigorous procedure described by Mr. Kirby.

The criterion under discussion would unquestionably be very useful in some practical cases. An extension of this criterion to systems in which the coefficients involve powers of t higher than the first would be of great value.

M. J. Kirby: Both discussions emphasize a very worthwhile point; a Nyquist plot is by no means the only method for determining the signs of the real parts of the roots of $P(s)$. Because Nyquist's method is used in many well-known American texts on servomechanisms, it was used in this paper. However, inspection of $P(s)$, or the use of a simple rule such as the one stated by Drs. Anderson and Caywood will suffice in many cases. In more complicated situations the Routh-Hurwitz criterion, as pointed out by Dr. Zadeh, and also by Dr. F. E. Bothwell[1] is more useful than a Nyquist diagram.

The comment that μ is real is correct Likewise, condition (3) should be corrected to agree with the main statement of the stability criterion in the paper, "...the real part of each pertinent $(-\lambda-1)$..."

There is definite need, as Dr. Zadeh points out, for a method of predicting relative stability, or the initial size of the transient response of varying-element servosystems. However, the present paper does not purport to give such a method; its stated object is to set forth a criterion for determining absolute or eventual stability. It should be pointed out that a constant coefficient servomechanism whose transient response exhibits violent overshoots initially but eventually dies out, would be classed as stable by the commonly used criteria of Nyquist or Routh-Hurwitz. The definition of stability used in the paper is parallel to that customarily used for constant-element systems.

Furthermore, it is not necessarily true that the asymptotic response of a system is of little practical interest. The transient responses of the systems of the examples of the paper, and many practical systems reach their eventual or asymptotic forms in a comparatively small number of time constants. The unstable examples (Figures 8, 10, and 13C) in particular illustrate this.

The advantage of dividing the original differential equation by t and letting t approach infinity, as suggested, in order to obtain the stability criterion is not clear. Obtaining a criterion is not an operation which must be repeated for each determination of stability; it need be performed only once and has been accomplished rigorously in the paper. Applying a limit process to a differential equation, in the manner suggested, before solving it, is not usually a rigorous procedure. This amounts to the limiting case of the constant coefficient approximation or "snapshot" procedure mentioned in the introduction. It does not give the complete asymptotic form of the solution (the $t^{-\lambda-1}$ factors are omitted) and it does not have any obvious warning within itself as to when its results are unreliable; as when some of the b_j terms are zero.

Variations of Tank Pressure with Transformer Loading in Sealed Transformers

E. W. TIPTON
MEMBER AIEE

IN A modern power transformer only the insulation consisting of oil and fibrous materials shows appreciable deterioration under normal operating conditions. It is, consequently, only natural that much effort has been applied to the problem of preventing or retarding this deterioration. Many schemes for this purpose have been devised; open air breathers, dehydrating breathers, conservators, gas-oil seals, sealed tanks, inert gas atmospheres, and thermosiphon clay filters, to name a few. These devices have one or two objectives which are: to prevent the entrance or to minimize the effects of moisture, or to exclude oxygen and minimize the effects of oxidation. The simplest method is to seal the transformer tank and, as is often the case, the simplest also is the equal in effectiveness of any of the methods. This has been demonstrated by direct comparison on life test.[1]

First applied to submersible network transformers, the practice of tightly sealing power transformers has been proposed as an industry standard for small and moderate sized transformers; those up to about 10,000 kva in rating. As a parallel development has come the welding on of covers to eliminate the main gasket. A definite trend toward solder sealed or welded bushings is another step toward the elimination of gaskets to better insure a tight tank.

When a transformer is tightly sealed with a gas space over the top of the oil surface, it is subject to variation in internal pressure during its operating cycle. Changes in temperature due to ambient changes and to heating from excitation and load losses cause the oil to expand, and produce heating of the gas. Both effects result in an increase in internal tank pressure. The variation of pressure as a function of load and ambient temperature is of interest, both to transformer designers and to transformer operators.

The calculation of pressure as a function of load is not a simple one. The principal factors involved are:

1. Oil expansion due to heating.
2. Pressure temperature effects on the gas.
3. Tank wall deflection.
4. Solubility of the gas in transformer oil.
5. Chemical reactions between the gas and transformer oil.

The effects of the first two of these factors may be easily and accurately calculated. Tank wall deflection is a relatively minor, though appreciable factor and it can be estimated empirically from test results with fair accuracy. Gas solubility and reaction with transformer oil are complex and difficult to calculate, but they play the major role in determining transformer pressure.

Effect of Oil Expansion and Gas Heating

The change in pressure due to oil expansion and gas heating may be calculated easily using the temperature coefficient of expansion of the oil and the gas laws.

If we let:

P = absolute pressure in the gas space, pounds per square inch
V = volume of gas space, cubic inches
T = gas temperature, degrees Kelvin
θ = average oil temperature, degrees Kelvin
v = volume of oil, cubic inches

These apply to conditions at some load which is being investigated.

P_0, V_0, T_0, θ_0, and v_0 have the same meaning as above, but apply to conditions at the time the transformer is sealed.

K = volumetric coefficient of expansion of oil per degrees centigrade
$R = V_0/v_0$ ratio of gas volume to total oil volume at sealing temperature, $T_0 = \theta_0$

By the gas law:

$$\frac{P_0V_0}{T_0} = \frac{PV}{T} \text{ or } P = P_0\frac{V_0}{V}\frac{T}{T_0} \text{ pounds per square inch}$$

The increase in oil volume due to its thermal expansion will be equal to the decrease in the gas volume and:

$$V = V_0 - K(\theta - \theta_0)v_0$$

$$P = P_0\frac{T}{T_0}\frac{V_0}{[V_0 - K(\theta - \theta_0)v_0]} \text{ or } P = P_0\frac{T}{T_0}\frac{R}{[R - K(\theta - \theta_0)]} \text{ pounds per square inch} \quad (1)$$

Based on the gas laws, the maximum pressure to be expected under normal operating conditions can be determined from the following considerations:

1. By the standards of the American Standards Association the maximum permissible oil rise at rated load is 50 degrees centigrade, and the average copper rise is 55 degrees centigrade.

2. For a given hot oil rise, the oil will have the highest average temperature in a transformer having the lowest hot spot gradient. If we assume the gradient to be 8 degrees centigrade, then the transformer hot spot rise will be 63 degrees centigrade.

3. The difference between hot copper and average copper is essentially the same as the difference between hot oil and average oil. If top oil rise is 50 degrees centigrade, this gives an average oil rise of $50 - 8 = 42$ degrees centigrade.

Paper 50-275, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 26, 1950; made available for printing September 11, 1950.

E. W. TIPTON is with Westinghouse Electric Corporation, Sharon, Pa.

Figure 1. Minimum and maximum tank pressures as a function of the ratio of air volume to oil volume

(A) Maximum pressures
(B) Minimum pressures

4. Maximum ambient for full load operation is 40 degrees centigrade.

5. Assume ambient at the time the transformer is sealed to be 20 degrees centigrade.

6. The thermal drop from the top oil to outside air is made up of three drops in series; from the oil to the gas in the top of the transformer, from this gas to the cover, and from the cover to the outside air. These three drops involve approximately the same surface areas and are approximately equal. On this basis, the air temperature rise will be two thirds that of the hot oil.

7. Transformer will be sealed at atmospheric pressure with the gas and oil at ambient temperature.

If these conditions hold:

$P_0 = 14.7$ pounds per square inch
T = two thirds hot oil rise plus ambient plus 273 = 346 degrees Kelvin
θ = average oil rise plus ambient plus 273 = 355 degrees Kelvin
T_0 = sealing ambient plus 273 = 293 degrees Kelvin
$\theta_0 = T_0 = 293$ degrees Kelvin
$K = 0.00074$ (approximately)
$P_{max.} = 17.4R/(R-0.046)$ pounds per square inch (absolute)

By a similar process of reasoning, the minimum pressure to be expected might be taken to apply to an idle transformer, such as an unexcited spare unit, in an ambient of −30 degrees Centigrade. For these conditions:

$P_0 = 14.7$ pounds per square inch
T = ambient plus 273 = 243 degrees Kelvin
$\theta = T = 243$ degrees Kelvin
T_0 = sealing ambient plus 273 = 293 degrees Kelvin
$P_{min.} = 12.2R/(R-0.037)$ pounds per square inch (absolute)

In Figure 1, the values of the minimum and maximum internal pressures are plotted as a function of the ratio of gas volume to oil volume in the transformer tank.

Figure 2. Test setup to determine effect of tank wall deflection

Effect of Tank Wall Deflection

Many power transformers of small and moderate rating are built in rectangular tanks. Flat sides of such tanks are braced to enable the tank to withstand test and operating pressures. Under pressure or vacuum, the flat unbraced portions of the tank wall are permitted to deflect within the elastic limit of the material. Deflection of the tank walls under pressure has the effect of increasing the tank volume and decreasing the observed pressure below what would be calculated by the methods discussed previously.

To determine experimentally the quantitative effect on pressure of tank wall deflection, a number of transformer tanks were tested with the simple test setup shown in Figure 2. A small reservoir was connected through a valve into the top of the sealed transformer tank. In the main tank cover were an overflow valve and a vacuum pressure gauge. Then with the main tank completely full of oil and a reserve supply of oil in the reservoir, the system was pumped up to a predetermined pressure after which the valve between reservoir and main tank was closed. The overflow valve is then opened and the amount of oil which flows out as the pressure returns to zero is a measure of the increase in volume of the tank due to pressure.

Rectangular tanks for transformers ranging from 150 kva to 1,500 kva were tested. These tanks had inside dimensions varying from 25 by 36 inches to 32 by 68 inches and heights from 64 to 126 inches. They were designed for a test pressure of eight pounds per square inch and had horizontal channel braces. In addition, one similar tank designed for complete vacuum was tested. The results of the tests are shown in curve form in Figure 3, curve B.

For tanks designed for an 8-pound test, the experimental data are very closely approximated by assuming that the increase in volume varies linearly from 0 to 1.4 per cent of the tank volume as the internal pressure varies from 0 to 8 pounds per square inch.

$$V_1 = V_0 + 0.00175(P-14.7)v_0$$

Letting $R = V_0/v_0$, then

$$V_1 = V_0\left(1 + 0.00175\frac{P-14.7}{R}\right)$$

where

V_1 = gas volume at absolute pressure P
V_0 = gas volume at atmospheric pressure
v_0 = oil volume

When designed for full vacuum, the tanks are more rigid and for the tank which tested as shown in Figure 3:

Figure 3 (left). Increase in tank volume due to pressure

(A) Tanks designed for 8 pounds per square inch test pressure
(B) Tank designed for 15 pounds per square inch test pressure

Figure 4 (right). Time-pressure curve for Test 1. Transformer oil filled at atmospheric pressure then sealed

(A) Calculated gas pressure
(B) Tested gas pressure

Figure 5. Time-temperature curve for Test 1. Transformer oil filled at atmospheric pressure then sealed

(A) Hot oil temperature
(B) Air temperature in gas space
(C) Average oil temperature

$$V_1 = V_0\left(1+0.0008\frac{P-14.7}{R}\right)$$

These figures are for a particular type of transformer tank and have no general application. They are of interest in that they apply to typical braced rectangular tanks which probably show the maximum to be expected for this effect. The tests show that the maximum increase in volume due to pressure is about 1.5 per cent of the oil volume. Normally the gas space in sealed transformers is about 10 per cent of the oil volume. The maximum tank volume expansion expressed in per cent of the gas volume is 15 per cent. From this, we can conclude that the measured gas pressure at a given load may be reduced a maximum of 15 per cent below the calculated value, due to tank wall deflection.

Effects of Gas Solution in Transformer Oil

Test Apparatus

To determine the effects of gas solubility on the internal pressure of sealed transformers, a series of load tests were run on a 500-kva transformer. A round case with heavy walls was used to eliminate the effects of tank wall deflection. Six thermocouples were installed; five in the oil, distributed from the top to the bottom of the case, and the sixth in the gas space above the hot oil. By assuming straight line temperature variation between adjacent thermocouples at different levels, the average oil temperature could be determined. For taking data, the test transformer was equipped with a vacuum pressure gauge and a visual oil level indicator. When filled with oil to the normal oil level at 20-degree centigrade temperature, the transformer case contained 212 gallons of oil and 29.1 gallons of gas.

Method of Testing

A total of 13 tests were made with certain procedures maintained constant for all. In each case, the core and coils assembly of the transformer was placed in a large tank and vacuum impregnated with oil. It was then placed in its own tank and filled with new oil and sealed, following which a pressure test was made to determine that the case was tight. After this preparation, a standard short circuit temperature run was made. At the start and at half-hour intervals throughout the test, measurements were made of gas space temperature, oil temperature at five different levels, and gas pressure. Measurements were continued during the heating period, while constant temperature was held for two hours, and after the load was removed until the transformer returned to ambient temperature. Tests were made under 13 different conditions of filling and initial gas pressure as shown in Table I.

Test Results

The test data are given in graphical form in Figures 4 to 10. Figure 4 shows the measured values of internal pressure during the test and the corresponding values calculated by equation 1, which neglects the solubility of the gas. Data are taken for test number 1 in which the

	After the first temperature run, additional nitrogen was added to bring pressure up to 3 psi and then three more temperature runs were made			

transformer was not vacuum filled and was sealed at atmospheric pressure. Values of hot oil, average oil, and gas temperature for this test are plotted in Figure 5. These curves are typical of those obtained on all the tests.

In Figure 6 the measured pressure curves are plotted for all the single run tests made with air in the gas space. The corresponding pressure curves for those tests with nitrogen in the gas space are given in Figure 7.

Figures 8 to 10 give the pressure time curves for the three repeated cycle tests. They apply respectively to the tests with air in the gas space when the transformer was not vacuum filled, when it was vacuum filled, and to the test with nitrogen in the gas space in which nitrogen was supplied until the oil was saturated.

Results Calculated From Test Data

In each of the tests the volume, temperature, and pressure of the gas in the gas space were known at the start of the test cycle. At each point in the test cycle the gas pressure and temperature were known by direct measurement. The corresponding volume can be calculated by subtracting from the original volume the calculated oil expansion based on the measured oil temperatures. If the gas volume at any point in the test is corrected to the same pressure and temperature which held at the start of the test, then the difference is the amount which went into solution. This volume can then be corrected to atmospheric pressure and a temperature of 25 degrees centigrade and expressed as a per cent of the oil volume at 25 degrees centigrade. Such calculations have been made for each of the tests for three conditions in the test cycle:

1. At the time of maximum pressure.
2. At the time of maximum temperature.
3. At the time where the transformer has again cooled to ambient temperature.

These results are shown in Table II. Except for the final test, test number 13, these figures do not represent the total solubility because the tests were made with only a limited amount of gas available. For test number 13, if the quantities of gas which went into solution in each of the four temperature cycles are added, a solubility by volume of 12.5 per cent is indicated for nitrogen at atmospheric pressure and 25 degrees centigrade. Any residual gas in solution after the vacuum treatment to which the oil was subjected would represent an error in the 12.5 per cent figure. In all cases where the gas used was air, the figures will be in error because of that part of the oxygen which reacted chemically with the oil. In practice, all of the oxygen will eventually be used up in this manner. Also, there is some error because an ordinary commercial vacuum pressure gauge was used and the figures are obtained by routine commercial test procedure rather than by laboratory measurements.

Conclusions

1. With commercial methods of processing, due mainly to the solubility of gas in transformer in oil, a transformer as delivered for use will have a load pressure characteristic greatly different from that calculated by means of the gas laws. This is true whether the transformer is or is not filled under vacuum. The maximum pressure under load will be reached before constant temperature is attained, and the maximum pressure will be lower than that calculated by the gas laws. After cooling to ambient, the pressure will be less than the sealing pressure.

2. If vacuum filled, then allowed to stand open for 24 hours before sealing, the results are about the same as when the transformer is sealed immediately. The gas does not quickly go into solution at ambient temperature with nonagitated oil. If, however, a vacuum filled transformer is given a standard temperature

Figure 9. Time pressure curve for Test 12. Oil filled under vacuum and sealed at atmospheric pressure. Repeated load cycle. Air in the gas space

Figure 10. Time pressure curve for Test 13. Oil filled under vacuum Sealed with nitrogen at an initial pressure of 8 pounds per square inch. Repeated tests with nitrogen pressure adjusted after each cycle, as marked at (A), (B) and (C)

run while open to the air, and then is sealed, it thereafter acts like a transformer which is not vacuum filled.

3. As illustrated by Figures 8 and 9, the pressure load characteristic of sealed transformers stabilizes after about one full load temperature test cycle. When not vacuum filled in the test transformer, which had a gas-to-oil ratio of 0.1375, the pressure ranged after stabilization between limits of −4 pounds per square inch and +3 pounds per square inch with the average oil temperature between limits of 20 and 65 degrees centigrade. When vacuum filled, the pressure ranged from −9 to −2 pounds per square inch for the same temperature limits.

4. After a transformer is vacuum filled, a considerable amount of gas must be added under pressure while the oil is hot before it becomes saturated with gas. In test number 13, Figure 10, the oil dissolved 12.5 per cent of nitrogen by volume corrected to 25 degrees centigrade and atmospheric pressure. Afterwards, on a temperature run load cycle, the pressure started at atmospheric and returned to atmospheric when again cooled to ambient temperature. Even in this case, the maximum pressure was reached before constant temperature was attained and the measured pressure was less than that calculated by the gas laws by approximately 18 per cent.

5. If negative pressures are to be avoided in sealed transformers, it is necessary to restore gas which is removed by vacuum filling of the transformer. This gas is not easily restored. A complete temperature run cycle with the gas space open will do it but this is not a practicable method. One suggested method is to charge the transformer with dry nitrogen to a positive pressure of from 6 to 8 pounds per square inch before it is placed in operation. This charge should then be repeated once or twice after the transformer has undergone a load cycle This practice is safe if the tank is protected with a relief valve set to operate at a pressure a little lower than the tank test pressure.

6. Another and simpler method of restoring gas to the oil is to provide the transformer with a relief valve to relieve excess external pressure. During normal operation after a few temperature extremes, sufficient air is admitted to saturate the oil to the extent that thereafter, no further adjustment will take place. The amount of oxygen admitted is too small to adversely affect the oil properties.

Discussion

F. J. Vogel (Illinois Institute of Technology, Chicago, Ill.): Mr. Tipton's paper is very interesting in showing the great effect of gas solubility in oil. Many small transformers for fairly high voltage, relatively speaking, are used for radar and other electronic device applications. They must be definitely free from corona under operating conditions, and large variations in temperature. Great difficulty was once experienced in their manufacture.

To obtain high dielectric strength, some thought it necessary to seal them as soon as they were filled, under extremely high vacuum. To allow for expansion, complicated devices, such as bellows, were used, and marbles were sometimes added to reduce the oil volume subject to expansion. An answer was actually much simpler. After filling under vacuum, if air was not allowed to go into solution in the oil, the dielectric strength was low and corona was found. So, a few-hours exposure to air was found necessary. Also, it was found that the amount of gas space could be absurdly small and still the actual pressure variations were small. In this connection, it is of interest that the dielectric strength of oil is very much a function of the gas in solution, and that after filling a transformer with oil under vacuum, some time allowance and exposure to air is necessary to develop full dielectric strength. Data regarding these effects have already been published in the past.

H. H. Wagner (Pennsylvania Transformer Company, Canonsburg, Pa.): This paper introduces a subject which is of interest to both manufacturers and operators of transformers. The author discusses primarily the effects on tank pressures of the oil expansion due to heating and of the pressure-temperature effects on the gas. It appears however, that the chief problem presented is that of negative pressures occurring on new transformers, and this effect, of course, is caused by the gas solubility in transformer oil.

The chemical reaction of nitrogen with transformer oil is negligible, but the gas solubility in oil is of great importance. Fortunately, the laws of solubility of gas, especially nitrogen in oil, while not so generally known, can be determined by practical methods.

Tests on the temperature effect of gas solubility show that with nitrogen over the oil at a pressure of one atmosphere at 25 degrees centigrade oil temperature, the solubility of the gas in the oil at the equilibrium is 9 per cent. At 80-degree centigrade oil temperature at the same pressure, the nitrogen in solution in the oil increases to 10 per cent. These values of gas volume are corrected to 25 degrees centigrade. It is noted that the increase in gas solubility is not due to increased volume of oil at the higher temperature since the increase in oil volume is 4 per cent for the same temperature range while the increase in volume of dissolved gas is 11 per cent.

These values for solubility are lower than the $12^1/_2$ per cent value given in the paper, probably due to the fact that these values are based on laboratory tests while the $12^1/_2$ per cent value is based upon commercial tests using commercial type gauges and equipment.

The pressure effect on gas solubility follows Henry's Law in that a linear relation applies from absolute zero pressure all the way up through pressures below and above one atmosphere. In other words, at absolute zero pressure (complete vacuum) the nitrogen solubility in oil is zero. At one atmosphere pressure, the nitrogen solubility is 9 per cent at 25 degrees centigrade. At 10 pounds per square inch gas pressure, the

Figure 1. Assembly of diaphragm relief device showing operation of vacuum relief valve

solubility is approximately 15 per cent at 25 degrees centigrade. Thus, the effect of pressure change is much greater than that of temperature on the solubility of gas in transformer oil.

The author's conclusion number 6 states that after a few temperature cycles with breathing the oil becomes saturated with air, and thereafter no further adjustments will take place. This depends upon the amount of gas space in the design of the transformer at the normal 25 degrees centigrade oil level and on the settings of the relief valves. Figure 1 of the paper shows that for the normal gas volume of 10 per cent, the pressure range is from —5.5 pounds per square inch to +17 pounds per square inch, which will occur if the tank is so well braced as to prevent tank wall expansion.

We prefer to use 15 per cent gas space which limits the maximum pressure to less than 10 pounds per square inch under the same conditions of operation, and, therefore, the pressure relief valve can be set at 10 pounds without permitting breathing.

The data in the paper show that the only appreciable reduction in the maximum positive pressure to be expected below the calculated value would be due to tank wall deflection, which is obviously a variable dependent upon the safety factor used in design of the tank. Therefore, an important and additional conclusion is that the tank must be designed for the maximum and not the final pressure during load cycles. Analysis of the data shows that the drop in pressure after the peak of the pressure curves during the heating cycle is due only to the gradual increase in the solubility of the gas in the oil at the higher pressures and temperatures.

For a complete analysis of this subject, we have found three very useful principles, which have been confirmed at least in part by other investigators.[1,2]

1. Expansion of transformer oil with temperature change is substantially the same whether or not it contains dissolved nitrogen.
2. Transformer oil at a given temperature has the same volume whether or not it is saturated with nitrogen.
3. The change in transformer oil volume as a result of changing gas pressure is negligible over the range in pressure encountered.

It might appear to be somewhat of a paradox that in filling the transformer with oil we use a vacuum process which in our factory removes over 99½ per cent of the air; and then we find that we want to reintroduce gas into the oil during operation. The reason for this is that, first of all, there are two purposes in removing all the air from the oil:

1. Air removal during filling is necessary as part of the process of removing the air from the spaces in and between the solid insulation in the transformer and thus to prevent air pockets in the insulation, which would greatly reduce the dielectric strength.
2. Vacuum filling also removes the suspended gas bubbles in the oil which lower the dielectric strength of the oil.

On the other hand, the air or gas which later enters the de-aerated oil through solution remains as dissolved gas which does not appreciably affect the dielectric strength of the oil, but is necessary for preventing excessive negative pressures during operation.

In any system for transformer oil preservation employing a sealed tank system, a certain amount of maintenance attention will be required to assure that proper sealing is maintained and that excessive posi-

Figure 2. Diagrammatic drawing of inert gas-oil seal system

tive or negative pressures do not develop. It would usually be impractical to frequently recharge the transformer with nitrogen, and therefore some type of a pressure-vacuum limiting device should be used. This requirement can be met by either a mechanical relief device, such as shown in Figure 1 of this discussion, which operates at fairly high pressure limits, or by a manometer principle system employing auxiliary tanks arranged as shown in Figure 2 of this discussion which not only provides an extremely simple and reliable pressure-vacuum relief in case of extreme temperature range of operation, but also considerably reduces the pressure range obtained in operation. Due to the much lower operating pressures obtained in the manometer type system, which is commonly known as the "gas-oil seal system," the maintenance problems of proper sealing and accessories are reduced to a minimum.

E. W. Tipton: The discussions by Mr. Vogel and Mr. Wagner bring up a number of interesting points and are very much appreciated. Both discussions, Mr. Wagner's in some detail, bring out the important consideration that restoring the gas to solution does not defeat the purpose of vacuum filling. It should also be emphasized, I believe, that vacuum filling is very necessary if the full strength of the transformer insulation is to be developed.

Mr. Wagner is of the opinion that the chief problem presented is that of negative pressures. The data given in the paper cover the principal factors affecting the pressure in sealed transformers, as these factors affect both positive and negative pressures. The effect of the thermal expansion of the oil and gas is to increase the internal pressure. Gas solubility in the oil and tank wall deflection decrease the pressure. Practically, the effects on the maximum pressure are more important than the negative pressures.

Also in Mr. Wagner's discussion it is stated, "The data in the paper show that the only appreciable reduction in the maximum positive pressure to be expected below the calculated value would be due to tank wall deflection, —". The test data actually show, as stated in conclusion number 6 of the paper, that even with oil saturated with gas, the maximum internal pressure is less than that calculated by about 18 per cent. The maximum reduction to be expected due to tank wall deflection is about 15 per cent which is in addition to the reduction due to solubility of the gas.

The author did not intend to make a comparison of methods of sealing, a subject not properly within the scope of the paper, but since the point is raised in the discussion, it should be pointed out that simply sealing transformers tightly eliminates the necessity for auxiliary tanks which add to the size of the transformers and in some cases, blanket surfaces needed for cooling. Also, sealed transformers do not require frequent recharging with nitrogen but at most, only the addition of gas during the first load cycle. As shown in the paper, a single temperature run cycle with gas supplied restores the gas removed by vacuum filling. The oil and insulation protection afforded with this simple system has been shown to be unexcelled.[1]

Use of Techniques from Electrical Analogues in the Study of Transmission Line Vibration

J. LUMMIS

A. KLOPFENSTEIN
ASSOCIATE AIEE

THE PHYSICAL components of a span of transmission line cable and its end supports can be studied by comparing it with an equivalent network of electrical components. An equivalent network for the cable span consists of distributed inductance and capacitance representing the electrical transmission line shown in Figure 5. The equivalent terminating network is determined by the mass of the insulators and the flexibility and friction in the supporting structure. The impedance to motion at supports generally does not equal the impedance of the span so that vibrational wave energy is reflected by these terminations. When waves of energy are trapped between two reflection points, energy will build up to destructive levels in standing waves from only a small input source. Similar conditions of reflection cause standing waves in radio transmission lines. Damage occurs at reflection points where direction and polarity of waves are changed in a restricted region. Electrical standing waves are undesirable in radio transmission lines and have been prevented with proper terminations, see reference 8(c). Techniques used in this field have been found applicable to the field of mechanical vibration. Mechanical impedance matching devices can be used, equivalent measuring techniques can be followed, and the design of tower, insulator string, and clamp system can be made with the idea of matching the impedance of the span and to stabilizing it against vibration. Using electrical techniques, work on a full scale test span has shown promising results in finding solutions to problems of mechanical vibration of transmission line spans.

A span of cable is excited into transverse motion by the wind. Its motional frequency is determined by its diameter and the wind velocity. Waves of transverse motion excited in the span, travel at a definite velocity determined by the mass per-unit length and tension in the span.[134] An electric transmission line is likewise excited so that waves of electric energy travel down the line. If there is negligible resistive loss and leakage in the line, velocity of wave travel is determined by distributed capacitance and inductance of the line, see reference 8(b). Linear density is analogous to distributed inductance and tension to the reciprocal of distributed capacitance. It can be shown that friction and resistance, transverse deflection and charge, transverse velocity and current, transverse force and voltage, potential energy stored in elastic deflection and electrostatic field energy and, also, kinetic energy stored in moving mass and electromagnetic field energy are analogous in the mechanical and electric systems, see reference 8(d).

Techniques of physical measurement are difficult in the light flexible system of vibrating span without disturbing the system. From the development of radio transmission lines and their terminations there has evolved means of measurement which show many phenomena existing in the electrical analogy.

The tendency toward oscillation of a terminated radio transmission line usually is expressed in terms of a voltage standing wave ratio. The more closely this ratio

Figure 3 (left). Untuned devices to prevent standing waves

Figure 5 (right). An equivalent electric network for a span of transmission cable

approaches unity, the more nearly perfect the radio transmission line has been terminated. Tendency toward oscillation also can be expressed in terms of the Q of the terminated system which is found by dividing the input impedance measured at resonance by input impedance measured at antiresonance. The Q ratio of a network is the total impedance looking into a network divided by the resistance seen at this point. The Q of a properly terminated transmission line is near unity. Impedance measured at resonance is the total impedance while antiresonant impedance is only the resistance, see references 8(a), 8(b), and 9. The Q of a mechanical system also can be found.

Tuned Impedance Matching Devices

Impedance matching devices to prevent electrical standing waves of voltage and current on very high frequency and ultra high frequency radio transmission lines fall into tuned and untuned types. The tuned type is most commonly used where matching need only be done for one frequency or narrow frequency band. These consist of tuning stubs, matching quarter wave length sections, re-entrant sections, and so forth.[9] There is very little energy dissipated in these devices. While adding resistance reduces their efficiency it also increases the width of the frequency band in which the devices are effective.

The Stockbridge damper is a device of this type. Its frictional losses reduce its resonant efficiency but increase its band of effectiveness. Den Hartog analyzes this effect in describing dynamic vibration absorbers, see reference 7(a).

These devices introduce a reflected wave into the system at a point one-quarter wave length from troublesome reflection points so that the introduced wave is diametrically out-of-phase with the unwanted reflected wave and has the proper amplitude to completely cancel the unwanted reflected wave.

Untuned Matching Devices

Electrical impedance matching devices of the untuned type are used where a large band of frequencies must be carried by a radio transmission line. They operate above a minimum cutoff frequency which is determined by the maximum physical dimensions of the device. Those that do not dissipate energy are usually sections of line where impedance is exponentially tapered along a length gradually changing from the impedance of the line to the impedance of the terminal device. Open wire radio transmission lines are often tapered in this fashion to match the impedance of untuned types of antennas. Tapered horns are often used to match the impedance of a microwave guide to the impedance of free space or match two types of wave guides, see references 5, 6, 9(d). Reflection occurs from all points in the taper because the impedance is continually changing. The action of reflection changes the phase of a wave 180 degrees and two waves which have been reflected from points 90 degrees apart on the taper will be 180 degrees out-of-phase, since one has travelled 180 degrees farther than the other, and cancellation will take place between these two waves. If the taper is of the correct exponential nature, it makes the amplitude of all reflected waves equal so that cancellation will be complete. Since cancellation is only complete between waves which are reflected from points 90 degrees apart, the cutoff frequency is one which makes the taper one-quarter wave length long.

Tapered armor rods and tapered-mouthed suspension clamps reduce standing waves in cables by the action described for the exponentially tapered electrical section. Since these devices are generally not designed with this action in mind, complete impedance matching is not obtained. However, any device which causes reflections to occur from points in a region near a troublesome reflection point will reduce standing wave ratios and the effective Q of the system. For the best

Figure 4. Operation of devices designed to set up waves for cancelling undesirable reflections

Figure 8 (right). Loci of test span resonant and anti-resonant motional impedance

results, the length of this region must be more than a quarter wave length at the lowest frequency at which the device is to be effective. As frequency is increased above the cutoff frequency the taper increases in angular length and as the taper length approaches infinity, the device will approach a perfect impedance match.

Festoon Type Matching Devices

Loose cables hung or festooned on transmission line cables near terminations have been successful in reducing standing waves in the span. Waves enter the festoon from the span, travel at slow speed and then are reintroduced into the span at the next point of attachment. If there are enough contact points along a region so that cancellation between these many reflected waves can occur, then standing waves will be prevented. It has been found that the festoon works best if tension in the loose material is negligible. This allows the festoon to be the most flexible and reduces the wave velocity in the festoon to a minimum.

Measuring Motional Impedance of a Test Span

To compare the effectiveness of damping or impedance matching devices it was decided that motional impedance tests should be made on a test span. This was done in the same manner that a communication or transmission line is tested to find how it acts when excited with the band of frequencies which it will transmit when in use. Measurements of input impedance variations were made electrically at the exciting source with changing frequency while deflection standing wave ratios were measured at the remote termination.

Description of the Vibration Exciter

In studying the vibration of transmission line conductors, a test span was vibrated with an electrical exciter to simulate wind induced vibration. This machine is similar to a dynamic loud speaker with the diaphragm removed and consists of a d-c excited electromagnet, and an armature coil which is flexibly mounted in its magnetic field and mechanically connected to the device to be vibrated. The vibration exciter was driven by applying a-c energy to the armature coil. Voltage, current, and power were measured with an electronic instrument which was accurate over the range of frequencies excited, and had no effect on the electrical source or load.

Before making measurements with the machine coupled to the cable, the armature was locked and low currents and voltages were applied to the armature over a range of frequencies that covered the expected vibrational frequencies. In this way the components of impedance due to the inductance and resistance of the machine were found so they could be separated from the effects of motion.

Information concerning the ease in which the span of cable could be set into resonance at different harmonic frequencies and with different damping devices was desired. The vibration exciter was coupled to the span of cable at a point which became a point of maximum motion when the cable was excited at a resonant frequency.

When current was made to flow through the armature coil, force was applied through a coupling rod to the cable, causing it to move. The applied force was approximately proportional to the current.

Voltage Generated by the Vibration Exciter

Motion of the armature coil through the field generates a counter voltage which will be in phase with and proportional to the instantaneous velocity of the armature and the cable at the point of attachment.

The phase angle and difference in magnitude between applied and generated voltage is determined by the frequency of

Figure 11 (left). Test span showing west dead end test support and instrument house

Figure 12 (right). Vibration exciter and tensioning lever and weight

excitation and the mechanical impedance of the system being vibrated. The electrical impedance of the armature also has an effect on the angular and amplitude difference between applied and generated voltage.

Cable Span Equivalent Circuit

An electrical equivalent circuit of the cable span, as measured through the exciter, is shown in Figure 5. Such a device has multiple resonance characteristics. The supports also resonate at high frequencies. The electrical impedance of the vibration exciter affects the resonant characteristics of the system at certain frequencies. Mechanical impedances are coupled mechanically into the exciter and appear in the electrical driving circuit where they can be measured. The total impedance of machine and cable varies with frequency, as shown in locus form, see reference 8(d).

Generated Voltage Forms Motional Impedance

The voltage generated by motion of the coil acts as an impedance to the flow of current which is called motional impedance. It is the difference between locked and total input impedance. The motional impedance locus alone without machine impedance is a circle. The diameter of a motional impedance circle is an indication of the power required to set a mechanical system into vibration at a given amplitude. The larger this diameter, the smaller the power needs.

Effect of Adding Friction

Damping devices added to the cable of the test span reduced the diameter of this circle. An effective measure of this circle diameter is the ratio of the total motional impedance at resonance to the motional impedance at antiresonance.

The friction in a mechanically oscillating system limits the maximum and the minimum impedances that occur at resonance and antiresonance respectively. When the oscillating system is modified so that more power is required to drive the system, this indicates an increase in mechanical friction which is similar to a decrease in electrical parallel resonant impedance or an increase in series resonant impedance.

Q Ratio of a Resonant Electrical Circuit

A measure of the quality of an electrically resonant circuit is the ratio of its impedance at resonance to its impedance at antiresonance. This quality ratio is called the Q of the circuit. The larger the value of Q, the less energy required to cause a given amplitude of oscillation.

The object in most studies of mechanical vibration is to determine how to reduce the amplitude of vibration for a given energy input. This would mean that the Q of a mechanically multiresonant oscillating system should be reduced toward unity. The effect of reducing the Q of a mechanical system can be measured through a vibration exciter so that the effectiveness of a damping or detuning device can be studied.

Figure 13. Vibration exciter on dolly coupled to test span

Reduction of Apparent Q Without Adding Resistance

An electric transmission line several wave lengths long is multiresonant if it is not terminated properly at load and source. If the line is to be used over a wide range of frequencies, the terminating devices must not be resonant. Terminations have been designed which prevent the transmission line from being a resonant length by designing a terminating section so that the impedance of the section exponentially tapers with length becoming equal to the impedance of the terminating equipment. Waves of energy are reflected at all points of changing impedance in the tapered section. These points are infinite in number and should extend over a minimum of a quarter wave length. There will be waves of energy of opposite polarity reflected by points which are one-quarter wave length apart causing cancellation of reflected energy to take place. This effectively prevents standing waves and resonance for frequencies at which the tapered section is several wave lengths long.

Reducing the Equivalent Q of a Multiresonant Mechanical System

Resonance can be prevented in the same manner mechanically by causing many points which reflect equal amounts of energy over at least a half wave length of a multiresonant system. Such devices were qualitatively tested on a small scale model span of string and then quantitatively tested by measuring the resonant and antiresonant motional resistance of a test span of actual transmission line material. Graphs and charts of some of these results follow in this paper.

Results of a Typical Test

Tests were made to study the vibrational stability of a test span of steel re-

inforced aluminum cable. Descriptions will follow of various graphs that present the data collected.

Locked Armature Test (Figure 7)

The armature of the vibration exciter was locked, as securely as possible, to the field structure. Power, current, and voltage were measured as the armature was excited over a range of frequencies. From these values the resistance and reactance were calculated.

The reactance curve is nearly a straight line. An extension of this line passes close to, but not through, zero ohms at zero frequency. The resistance increases almost linearly above 60 cycles. Below 60 cycles, the resistance curve falls away from the straight line. The increase in resistance with frequency is caused by increasing iron losses. The knee in the resistance curve may be due to incomplete locking of the armature which would allow more mechanical friction loss at the lower frequencies where inertia has a lower restraining effect.

Maximum and Minimum Motional Impedance (Figure 8)

These curves are a loci of maximum and minimum motional impedance points that occur at span resonance and antiresonant frequencies. This graph plots motional impedance versus frequency over a fairly wide range of frequency. Vibration amplitude could not be held constant over this wide range of frequencies.

Below 60 cycles the nearly parallel lines indicate motional impedance of the span with various devices added. The lower the maximum resistance that occurs at resonance, the more stable the span. Different devices reduce maximum impedance by different amounts. Above 60 cycles per second the impedance loci tend to join, and above 90 cycles per second, they all begin to increase to approximately the same value. For frequencies above 90 cycles per second the supports, over which the cable is strung, seem to be in resonance and to move nearly as much as the cable.

The minimum motional impedance occurs at antiresonance. Since almost no motion of the cable occurs at antiresonance, the motional impedance is nearly the same as locked impedance. Metering errors sometimes are as large as the small quantities being measured, so there is a wide variation in the data for minimum motional impedance. As frequency increases, minimum and maximum motional impedance approach each other, becoming nearly coincident above 150 cycles.

The increase in minimum impedance at antiresonance with increasing frequency is due to the increased rate of energy absorption due to hysteresis losses of bending and stretching. This same effect reduces maximum impedance at resonance. The reduction of maximum impedance is limited by the antiresonant minimum impedance. When these two limits are close together, the cable becomes very stable.

When the supporting structures are resonant they receive energy from the cable and are damaged. There actually have been reports of tower damage where bolt holes and bolts have been worn, members broken and nuts worked loose due to vibration. These were in locations where high velocity winds have excited vibrations and set parts of the tower in resonance.

If the tower receives energy from the span and is set into motion, it does prevent span resonance.

Impedance with Changing Amplitude (Figure 9)

This graph shows loci of maximum impedance occurring at resonance near 29 cycles per second in which the maximum amplitude was varied by controlling the power supplied to the span. This graph shows how motional impedance varies with amplitude on the free span and the damped span. The standing wave ratio is the ratio of maximum to minimum deflection measured at loop center and at nodes.

A graph such as this was plotted for each of several frequencies between 20 and 40 cycles per second to determine data for graphs of Figures 10.

The resistance of most of the devices decreased with amplitude. If the opposite were true, very destructive amplitudes would build up. The horizontal line for the 18-foot ropes indicates little change of resistance with amplitude. The lower the impedance locus, the more nearly its slope approaches zero while remaining negative, the more effective the device.

Fixed Amplitude—Variable Frequency Impedances (Figure 10)

The graph is similar to Figure 8, except that data is plotted for 0.05-inch maximum deflection at loop centers for a smaller range of frequencies. In this region most of the data tends to fall in a straight line.

Analysis of Graphs

The purpose of the test was to explore this method of investigation of vibrational stability and to test the stabilizing effect of terminating a test span of steel reinforced aluminum cable in a section loosely covered with small wire rope.

The rope covered section acts as a region of reflection instead of the point of reflection that occurs at the mouth of a suspension clamp. The loose rope tends to move out-of-phase with the cable. These motions cause impacts between the two which set up reflections at all the points of contact. Graphs indicate the effectiveness of the loose rope stabilizer. These data show that the longer the section and the greater loose mass added, the more effective the device.

Conclusion

Electrical analogues are being used to study many vibration problems and can also be applied to the study of transmission line vibration. A very high frequency or ultra high frequency radio transmission line is analogous to a span of transmission line cable and the tendency toward oscillation often found in a radio transmission line is due to the low rate of energy dissipation in the line and incorrect impedance at terminations. This is also true for a span of cable. Suppression of the electrical standing waves has been accomplished with electrical devices whose theory of operation has been tested with electrical techniques. This theory for electrical devices also fits analogous mechanical devices which have been used to reduce vibration in transmission line spans. Impedance matching better describes the operation of these mechanical vibration reducers than the term damper. Electrical theory shows that transmission line dampers do not operate primarily by dissipating energy. Friction in these devices reduces their maximum resonant effectiveness although it widens their effective frequency spectrum. Electrical testing techniques can be carried out mechanically to find the mechanical standing wave ratio and Q of a span. Finally, it has been shown that improved vibration reducing devices can be designed and tested using methods analogous to proved electrical techniques.

Determination of Reserve Capacity by the Probability Method

G. CALABRESE
MEMBER AIEE

THE probability method of determining generating reserve capacity has received a great deal of attention in the past few years. A number of papers, by different authors, have been published during the same period, attacking the problem from different angles and describing different general methods of calculation. In a paper[1] presented at the AIEE Midwest general meeting in Chicago in 1947, the author described a method for determining the reserve capacity of a system taking into consideration the shape of the load duration curve. This permitted to check, in a rational manner, the variation of the reserve requirements of a system with the changing character of the load. The method given in that paper is general, and applies regardless of shape of load duration curve.

Since calculations usually are laborious, it was suggested at that time to replace the actual load duration curve with a straight line or portions of straight lines. By doing so, calculations are greatly simplified. However, great as the simplifications may be, calculations still remain laborious, particularly in the general case of a system composed of units of diverse sizes and outage rates. In the practical application of the method, there are cases when it is possible to replace the actual system with a system composed of units all of the same size and outage rate, without great sacrifice in the accuracy of the results. This replacement further simplifies calculations and, in addition, permits to precalculate a set of key curves from which the reserve requirements of a system can readily be determined. In those cases where the system cannot be replaced by one composed of units of the same size and outage rate the curves can be used to obtain a quick preliminary answer to a reserve problem, an answer which can be checked later on when more time is available.

It is one of the purposes of this paper to further develop the exact expressions given in the previous paper[1] for the accurate determination of the reserve requirements of a system, and to give curves for the quick determination of the same reserve under the above-mentioned assumption that all units are of the same size and outage rate. The mathematical development for both the exact expressions and the curves is given in the Appendix.

In the application of the probability method to reserve problems, it is essential to establish some indexes for measuring the level of service reliability corresponding to a given reserve. A number of different indexes have been proposed or used for this purpose. The question then arises: what are the merits and disadvantages of each?

It also is the purpose of this paper to give a comparative discussion of three indexes of service reliability, namely:

A. *Probability of loss of load.* This is defined as the fraction of any period of time during which loss of load may be expected to occur due to forced capacity outages in excess of reserve. It can also be expressed as an expectancy of one day's loss of load every so many years. Expressions for calculating it are given in the Appendix.

B. *Expected energy loss per kilowatt of maximum load per year.* This is defined as the expected kilowatt-hours per kilowatt of maximum load per year, that cannot be supplied to the load because of forced capacity outages in excess of reserve. Expressions for calculating it are given in the Appendix.

C. *Expected energy loss per kilowatt of installed capacity per year.* The definition of this index is similar to (b), and expressions for calculating it also are given in the Appendix.

As a result of the discussion it is recommended that the probability of loss of load, introduced at the 1947 meeting, be retained and given preference.

The Load Duration Curve

The load duration curve referred to in this paper is the one obtained on the basis of the daily maximum loads having 365 points per year. The curve may be based on the actual daily maximum loads, in which case, more appropriately, it may be

Duration curve of 1-hour peak requirements

Paper 50-280, recommended by the AIEE Power Generation and System Engineering Committees and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted November 3, 1949; made available for printing September 25, 1950.

G. CALABRESE is Professor of Electrical Engineering at New York University, New York, N. Y.

Figure 2. Probability of loss of load for various numbers of units all of the same capacity assuming a straight line load duration-curve, an outage rate of $q = 0.02$, and a daily maximum load ratio $l = 0.5$

called the "daily maximum load duration curve." If this curve is used it will be necessary, after the contingency reserve has been determined, to check its adequacy for overhaul requirements, taking into consideration the cycle and duration of the overhauling period of the units involved.

For most practical cases, however, it will be sufficient and simpler to use a load duration curve based on the actual maximum daily loads plus requirements for overhaul.

The curve that is thus obtained may be called the "daily maximum load-overhaul duration curve." Figure 1 gives an example of one such curve, together with a straight line which may be used to replace it. It should be clearly understood that the use of the daily maximum load-overhaul duration curve introduces some duplications and errors in the results. It is believed that in most cases these errors are not serious. However, in doubtful cases, the reserve of a system should be determined on the basis of the daily maximum load duration curve.

Corresponding to the daily maximum load duration curve is the daily maximum load ratio given by:

$$\frac{\text{Sum of all daily maximum loads}}{365 \times \text{yearly maximum load}}$$

Similarly, the ratio corresponding to the daily maximum load-overhaul duration curve, which may be called the daily maximum load-overhaul ratio, will be defined by:

$$\frac{\text{Sum of all daily maximum loads plus overhaul requirements}}{365 \times \text{yearly maximum load plus overhaul at peak time}}$$

In the following discussion, for simplicity, reference will be made only to the daily maximum load duration curve and to the daily maximum load ratio "l", it being understood that the conclusions apply both to duration curves and ratios, exclusive or inclusive of overhaul requirements.

Figure 3. Probability of loss of load as for Figure 2, excepting that $l = 0.7$

Figure 4. Probability of loss of load as for Figure 2, excepting that $l=0.9$

Curves of Probability of Loss of Load and Energy Loss Requirements

The curves of Figures 2, 3, 4 have been plotted, using the methods outlined in the Appendix. Based on an outage rate, $q=0.02$, these curves give the probability of loss of load in function of the total capacity as a fraction of maximum load for 5, 10, 15, 20, 30, 50, and 100 units, all of the same capacity, and for values of the daily maximum load ratio equal to 0.5, 0.7, 0.9, respectively. If the daily maximum load ratio is equal to 1.0, the probability of loss of load coincides with the probability of outage in excess of reserve given in Table I of the 1947 paper.[1] Figure 5 gives the energy loss expectancies for 10, 15, 20, 30, 50, and 100 units, all of the same capacity, outage rate $q=0.02$, and daily maximum load ratio $l=0.5$ and 0.9, respectively. For intermediate values of l, the energy loss expectancies within the range of Figure 5 are proportional to $1/1-l$.

The curves of Figures 2 and 5, inclusive may be considered as key curves for an outage rate $q=0.02$, since from them, by appropriate replotting, it should be possible to obtain loss of load probabilities and energy loss expectancies for any practical value of n, the number of units, and l, as illustrated in Figure 6.

Limitations

The use of a load duration curve, based on daily maximum loads for the determination of indexes of level reliability, ignores the hourly fluctuation of the load. The various indexes thus obtained implicitly assume that each maximum daily load lasts throughout the day. For these reasons, strictly speaking, for systems having hourly load curves of radically different character, the indexes of service reliability thus calculated are not com-

Figure 5. Energy loss expectancy for 10, 15, 20, 30, 50, and 100 units all of the same capacity, straight line daily maximum duration curve, outage rate $q=0.02$, and daily maximum load ratio $l=0.5$ and 0.9

parable. For these extreme cases, a load duration curve based on hourly maximum loads should be used, with minor changes in the formulas of the Appendix derived on the basis of daily maximum loads. If an hourly load duration curve is used, however, it may not be altogether possible to replace the actual curve with a single straight line. Of course, in such cases, it should be possible to use two or more portions of straight lines with some additions to the complexity of the solution, which, however, seem hardly justifiable by the very nature of the problem. In the event that the replacement with a single straight line is possible, the expressions for the energy loss expectancies may be obtained by replacing (in the formulas of the Appendix) T with $24T$, so that the energy loss expectancy will be given, respectively, in kilowatt-hours, kilowatt-hours per kilowatt of maximum load, and kilowatt-hours per kilowatt of installed capacity.

Otherwise, an approximation to the energy loss expectancy in kilowatt-hours, kilowatt-hours per kilowatt of maximum load, and kilowatt-hours per kilowatt of installed capacity, respectively can be obtained from the expressions obtained on the basis of the daily maximum load curve, Sections 4 and 5 of the Appendix, by replacing T with $24TL$. Here L should be the ratio between the sum of the kilowatt-hours loss, taking into consideration the hourly variation of the load, and the kilowatt-hours loss assuming each daily peak constant throughout the day. The calculation of this factor would involve difficulties hardly justifiable by the nature of the problem. It is therefore suggested that, whenever it is necessary to include the effect of the hourly load variations in calculating the energy loss expectancies, the average of the daily load factors be used in place of L. Within the limits of the foregoing approximation, the product of L by the energy loss expectancy, as a fraction of the possible maximum load energy, gives the energy loss expectancy, as a fraction of the actual load energy.

Which Index of Service Reliability?

This is a question of great practical importance. In the early stages of the development of the probability method for determining reserve, the probability of outage in excess of reserve was used as an index of service reliability. The period of time was taken equal to the duration of a peak season, that is, approximately 100 days.

The concept of loss of load probability based on the load duration curve was not used until very recently.

Of the various indexes of service reliability that either have been used or proposed, the energy loss expectancy in kilowatt-hours per kilowatt of maximum load per year, based on an hourly load duration curve, is the most precise index because it more accurately reflects the effect of load changes. As an alternative, less accurate but easier to calculate, the energy loss expectancy in kilowatt-hours per kilowatt of maximum load, per year may be calculated on the basis of the daily maximum loads, assuming that each daily maximum remains constant throughout the 24 hours. Evidently, this is equal to the energy loss expectancy in kilowatt-days per kilowatt of maximum load per year (equations 11 and 15 of the Appendix) multiplied by 24, in order to express it in the more familiar terms of kilowatt-hours. As noted previously, the latter approximate index of service reliability can be multiplied by the average of the daily load factors in order to obtain a more accurate approximation.

The probability of loss of load as an index of service reliability is not as accurate a measure of service reliability as the kilowatt-hours per kilowatt per year, or the kilowatt-days per kilowatt per year. However it has the advantage of being easier to calculate and, for the problem under discussion, should give entirely satisfactory results. To state that the expectancy of loss of load is, say, one day in 25 years seems to carry a more definite idea than to say that the expected energy loss is 0.018 kilowatt-hours per kilowatt of maximum load per year, or that the expected energy loss is 0.000206 per cent of the possible maximum kilowatt hours use of the load. Unquestionably, however, either one of the last two expressions would give a more accurate measure of the expectancy.

From the expressions derived in the Appendix for loss of load probability and the energy loss expectancy it is evident that there is no definite relationship between the former and the latter.

What Level of Service Reliability?

The next question in line of importance is, of course, how much reserve must be provided to insure adequate service? As pointed out on other occasions, the question of what degree of service reliability must be provided in a particular situation depends entirely on local conditions and personal judgment. Under emergency conditions the corrective measure is available of lowering the voltage which, within certain limits and if not used too often, may be relied upon to relieve the situation. Generally speaking, it seems altogether reasonable to assume that a reserve giving a loss of load expectancy of 1 day in, say, 50 years or a probability of loss of load of 0.0000548, after reduction of voltage, should be satisfactory.

Published information indicates that voltage can be safely lowered by 5 per cent and that approximately a 1 per cent drop in load is obtained for every 1 per

Figure 6. Reserve requirements versus number of units. Loss of load expectancy of 1 day in 50 years, assuming a straight line load duration curve $q = 0.02$, and a daily maximum load ratio $l = 0.5, 0.8, 0.9$

cent drop in voltage, assuming that voltage regulators, where used, have been made inactive. If voltage is reduced, to alleviate the situation under emergency, two pertinent questions arise which require full consideration, namely: with a given reserve, what is the expected frequency of voltage reduction, and what is the effect on this frequency of the number of units of the system? In order to answer these two questions, it will be noted that, as shown in Figure 7, a reserve R_0', as a fraction of the maximum load *Lam* without voltage reduction, is equivalent to a reserve of

$$R_0'' = \frac{0.05 + R_0'}{0.95}$$

as a fraction of the maximum load 0.95 *Lam*, obtaining with a 5 per cent voltage reduction. It follows that, in order to obtain a reserve R_0'' with 5 per cent voltage reduction, it will suffice to provide a reserve $R_0' = 0.95R_0'' - 0.05$ without voltage reduction. Thus, a system of 20 units having an outage rate $q = 0.02$ and a daily maximum load ratio $l = 0.8$ requires a reserve of approximately 0.21 times the maximum load in order to provide the stated level of service reliability of 1-day loss of load expectancy for every 50 years. If advantage is taken of the 5 per cent voltage and load reduction, the reserve to be provided as a fraction of the maximum load without voltage reduction is, from the above relation: $0.20 - 0.05 = 0.15$. This is the required installed reserve as a fraction of the maximum load *Lam* without voltage reduction. To it corresponds a probability of loss of load of 0.00049, or a loss of load expectancy of 1 day for every 5.6 years. This means that, with 20 units and an installed reserve equal to 0.15 the maximum load, the expectancy of having to drop voltage up to 5 per cent is 1 day for every 5.6 years.

If, on the other hand, the system has five units—assuming the same outage rate $q = 0.02$ and maximum load ratio $l = 0.8$—the required reserve is 0.80 the maximum load. By taking advantage of the 5 per cent voltage reduction as before, the installed reserve is reduced to 0.71 the maximum load. To this reserve corresponds a probability of loss of load of 0.000061 or a loss of load expectancy of 1 day for every 45 years, a value altogether different from the value obtaining with 20 units.

From this comparison it is seen that, starting with the same level of reliability after the 5 per cent voltage reduction, the probability of voltage drop within the 5 per cent limit depends on the number of units, being smaller the smaller the number of units. Tentatively a drop of voltage expectancy, within the 5 per cent limit, of 1 day for every 5 years in general seems altogether satisfactory. With a large number of units, however, the probability of voltage drop may become unduly large. In such cases it may become necessary to increase the reserve in order to increase the number of years per day of load to the level stated before. For instance, with a system of 50 units, $q = 0.02$ and $l = 0.8$, the reserve required with no voltage reduction is 0.11 the maximum load. With 5 per cent voltage reduction the installed reserve reduces to 0.0545 the maximum load without voltage reduction. The corresponding probability of voltage reduction within the 5 per cent limit is 0.0014, an expectancy of 1 day for every 2 years. This value in itself is not excessive; however, local factors, such as the degree of automatic voltage regulation used, may make it necessary to increase the reserve to something of the order of 0.075 in order to decrease the above expectancy to 1 day for every 5 years. The actual value should be determined after evaluating all local factors involved, making use of the information available from past experience.

Figure 7. Straight line daily maximum load duration curve used in deriving the expressions of the various indexes of service reliability

Other Possible Applications of the Probability Method

It is true, as stated previously, that the probability method has received recently a great deal of attention yet there are still a number of possible problems to which, in the author's opinion, the probability method can be applied to great advantage: reserve and water utilization of hydro-systems, proper allocation of reserve savings derived from interconnections, rationalization of feeder reserve practices, and economic evaluation of alternative schemes of supply. The author is of the opinion that hydro-systems are ideally suited to the application of the probability method in so far as their reserve and water utilization are concerned. Perhaps this is already done. However, as far as the author has been able to learn, very little use is made in this field, at present, of the probability method.

How consistent are the feeder reserve practices followed by the various companies? The probability method should prove a powerful tool in answering this question. In regard to the economic evaluation of alternative schemes of supply, the author likes to close this paper by repeating a statement made in the paper presented at the 1947 meeting:[1]

"Apart from the application of the probability theory to the determination of an appropriate absolute level of service reliability for a group of units connected to the same bus, there is another class of problems for the solution of which the probability theory seems especially well suited. This class of problems concerns the evaluation of the relative reliability of alternative plans. What is the reliability gained by increasing or decreasing the reserve capacity of a group of units? By changing the size and connection of ties? By using a common header for a group of boilers? To the analysis of problems such as these, the probability theory is well adapted. It places, so to say, the alternative schemes in their proper relative positions from the standpoint of reliability."

The essence of this statement has been repeated on other occasions and is repeated here to emphasize one fact, namely: the immense economic value of

Figure 8. Energy loss caused by a capacity outage $O_k \leqslant R_0+2(1-l)Lam$

the probability method in comparing alternative schemes. It is rather strange that we should have started by using, and should continue to use, this method mostly for the determination of reserve capacity, requiring the setting of absolute values of indexes of service reliability, the most difficult to establish and interpret, and should at the same time fail to apply it in comparing alternative schemes involving only relative values of indexes of service reliability of much easier interpretation.

Conclusions

These may be summarized as follows:

1. It is recommended that loss of load probability be used as an index of service reliability.

2. Curves are given for the quick determination of the reserve requirements of a system for any given value of the daily maximum load ratio and any desired level of service reliability.

3. It is suggested that a level service reliability, corresponding to a loss of load expectancy of 1 day in 50 years after reduction of voltage, be used for general purposes.

4. Expressions are given in the Appendix for the accurate calculation of the reserve of a system assuming a straight line daily maximum load duration curve.

5. The two terms "daily maximum load ratio" and "daily maximum load-overhaul ratio" are defined and suggested for use in determining reserve capacity by the probability method.

In closing, the author wishes to point out the fact that this paper deals exclusively with installed reserve.

Appendix

In the 1947 paper,[1] it was shown that the contribution of a capacity outage O_k to the system probability loss of load in given by either $P_k\Delta_k$ or p_kt_k. Here P_k is the probability of capacity outages in excess of O_k, p_k is the probability of a capacity outage exactly equal to O_k.

$$\Delta_k=(t_{k+1}-t_k)$$

is the interval of time, as a fraction of the period, between the two successive capacity outages, O_k and O_{k+1}, and is obtained from Figure 7 where C is the total capacity of the system, t_k is the fraction of the period during which loss of load occurs with a capacity outage O_k. As shown also in the 1947 paper, the system probability of loss of load, P_s, is obtained by adding the products $P_k\Delta_k$ or p_kt_k for all possible values of O_k, that is, by:

$$p_s=\Sigma P_k\Delta_k \text{ or } P_s=\Sigma p_kt_k$$

When a straight line load duration curve is used, both expressions are susceptible of simplification. However, only the second expression will be fully developed here for two cases, namely: the general case when the system is composed of diversified units; and the special case when the units of the system are of the same size and outage rate.

1. General Case—System Composed of Diversified Units

Let, in Figure 7(*a*), *Lam* be the maximum and *KaLam* the minimum loads and let it be assumed that the load duration curve is a straight line joining the two points, *Lam* and *KaLam:*

The daily maximum load ratio as a fraction is given by:

$$l=\frac{Lam+KaLam}{2Lam}=\frac{1}{2}(1+Ka) \tag{1}$$

from which

$$Ka=2l-1 \tag{2}$$

Evidently the minimum practical value of *Ka* is zero, to which corresponds a minimum value of the daily maximum load ratio l equal to 0.5.

If R_0 is the reserve capacity at peak time from Figure (7A), it is obtained:

$$t_k=\frac{O_k-R_0}{(1-Ka)Lam}=\frac{O_k-R_0}{2(1-l)Lam} \tag{3}$$

The magnitude of O_k may fall in one of the following three cases:

$O_k \leqslant R_0$ (Case A)
$R_0<O_k\leqslant R_0+2(1-l)Lam$ (Case B)
$O_k>R_0+2(1-l)Lam$ (Case C)

Evidently, if $O_k \leqslant R_0$, Case (A), no loss of load will occur. Under Cases B and C loss of load occurs. The system loss of load probability is then the sum of the two probabilities of loss of load obtaining for all values of O_k falling in the limits of Cases B and C and is calculated as follows:

Capacity outages O_k such that $R_0<O_k\leqslant R_0+2(1-l)Lam$ (Case B)

These cause loss of load during the time t_k. Let p_k be the probability of losing exactly the capacity O_k. Their contribution to the system loss of load probability is:

$$\sum^{b} p_kt_k=\frac{1}{2(1-l)Lam}\sum^{b} p_kO_k-\frac{R_0}{2(1-l)Lam}\sum^{b} p_k \tag{4}$$

It will be noted that $\sum^{b} p_kO_k$ is the expectancy in the interval R_0, $R_0+2(1-l)Lam$. It can be calculated by subtracting from the total expectancy, the sum of the expectancies corresponding to outages outside of the interval.

Similarly $\sum^{b} p_k$ is the total probability of capacity outages in the same interval. It can be calculated by subtracting from 1 the total probability of capacity outages outside of the interval.

Capacity outages O_k such that $O_k>R_0+2(1-l)Lam$ (Case C)

The contribution of these capacity outages to the system loss of load probability is $\sum^{c} p_k$.

In the foregoing expressions, $\sum^{b}$ indicates that the summation extends to all values in the interval (Case B), and $\sum^{c}$ indicates that the summation extends to all values in the interval (Case C).

If the various capacities are expressed as fractions of the maximum load, as shown in Figure 7(B), it is obtained:

$$O_k'=\frac{O_k}{Lam}\ ;\ R_0'=\frac{R_0}{Lam}$$

Equation 3 for t_k becomes:

$$t_k=\frac{O_k'-R_0'}{2(1-l)} \tag{5}$$

The three ranges of Cases A, B, and C of capacity outages will become:

$O_k' \leqslant R_0'$ (Case A)
$R_0'<O_k'\leqslant R_0'+2(1-l)$ (Case B)
$O_k'>R_0'+2(1-l)$ (Case C)

Under Case B from equation 4 the probability of loss of load becomes

$$\sum^{b} p_kt_k=\frac{1}{2(1-l)}\left\{\sum^{b} p_kO_k'-R_0'\sum^{b} p_k\right\} \tag{6}$$

Under Case C the probability of loss of load becomes $\sum^{c} p_k$.

2. All Units Are Similar and of the Same Capacity

Under these conditions let C be the total capacity of the system of n units all of the same capacity C_1. It is:

$$C = nC_1 = R_0 + Lam = \left(1 + \frac{R_0}{Lam}\right) Lam = (1 + R_0')\,Lam$$

The total capacity C and the capacity of each unit, expressed as a fraction of the system maximum load Lam, are:

$$C' = \frac{C}{Lam} = 1 + R_0'; \quad C_1' = \frac{C'}{n} = \frac{1 + R_0'}{n}$$

An outage of k units causes a capacity outage, $O_k = kC_1$. Thus:

$$O_k' = \frac{kC_1}{Lam} = \frac{k}{n}(1 + R_0')$$

and equation 5 becomes:

$$t = \frac{1}{2(1-l)} \left\{ \frac{k}{n}(1 + R_0') - R_0' \right\} = \frac{1}{2(1-l)} \left\{ \frac{k}{n} - R_0'\left(1 - \frac{k}{n}\right) \right\} \quad (7)$$

The three ranges of Cases A, B, and C will become:

$$k \leq \frac{R_0'}{1 + R_0'} n \quad \text{(Case A)}$$

An outage of k units, where k is any integer from 0 to the maximum value satisfying the above relation, causes no loss of load.

$$\frac{R_0'}{1 + R_0'} n < k \leq \left\{ 1 - \frac{(2l-1)}{1 + R_0'} \right\} n \quad \text{(Case B)}$$

That is, the range (Case B) includes all outages of k units larger than

$$\frac{R_0'}{1 + R_0'} n$$

and equal to, or smaller than,

$$\left\{ n - \frac{(2l-1)}{1 + R_0'} n \right\}$$

The contribution to the probability of loss of load in this range is given by:

$$\sum^{b} p_k t_k \frac{1}{2(1-l)} \left\{ \frac{1 + R_0'}{n} \times \sum^{b} p_k k - R_0' \sum^{b} p_k \right\} \quad (8)$$

Evidently this contribution to the probability of loss of load can be calculated directly as the sum of the products $p_k t_k$, using equation 7 to calculate t_k. From equation 8, it is seen that for constant number of units n and reserve R_0' the contribution to the probability of loss of load in this range is proportional to $1/2(1-l)$.

$$k > \left[1 - \frac{(2l-1)}{1 + R_0'} \right] n \quad \text{(Case C)}$$

The contribution to the loss of load probability due to capacity outages of a number of units k satisfying the above relation is $\sum^{c} p_k$.

As the number of units increases, and for values of l not close to 1.0, say, between 0.5 and 0.9, the contribution to the loss of load probability due to capacity outages in the range (Case C) decreases and for a sufficiently large number of units becomes negligible. Under these conditions, as seen from equation 8, the total probability of loss of load is proportional to $1/2(1-l)$.

If the maximum load ratio is equal to 1, the interval, Case B, reduces to zero and the probability of loss of load reduces to that computed as under Case C.

The loss of load probability curves, such as those shown in Figures 2, 3, 4, obtained by plotting probability of loss of load versus total installed capacity as a fraction of maximum load, for constant number of units n and daily maximum load ratio l, will be continuous curves with discontinuity points in their slope taking place whenever either the lower limit

$$\frac{nR_0'}{1 + R_0'}$$

or the upper limit

$$\left\{ 1 - \frac{(2l-1)}{1 + R_0'} \right\} n$$

of the range (Case B) is equal to an integer. Thus, for increasing values of R_0', a break in the continuity of the slope of the curve for a specified n, regardless of the value of l, will occur when

$$\frac{nR_0'}{1 + R'} = n_1, \text{ or } R_0' = \frac{n_1}{n - n_1}$$

for all values of $n_1 = 1, 2, 3, \ldots (n-1)$. Other breaks, due to a change in the upper limit of the range (Case B), occur for all values of R_0' satisfying the relation:

$$n \left\{ 1 - \frac{2l-1}{1 + R_0'} \right\} = n_2, \text{ or } R_0' = \frac{n_2 - 2n(1-l)}{n_2}$$

where n_2 is a positive integer smaller than n. In using these formulas only the value of n_1 and n_2, corresponding to significant outage probabilities, need be considered.

3. Limiting Case When the Number of Units Becomes Very Large

Units are all similar and of the same capacity. As the number of units, n, becomes large approaching infinity, the probability of having continuously a number of units qn out approaches unity, at the same time as $n \to \infty$, the probability of larger outages than nq, approaches zero. The value qn, therefore, represents the very minimum theoretical reserve of the group, attainable only when $n = \infty$. If the reserve is nq units, the maximum load will be pn units, so that the reserve as a fraction of the load is:

$$R_0' = \frac{q}{p}$$

This is, then, the minimum theoretical reserve of a group of units n as n approaches infinity. If $q = 0.02$, $R_0' = 0.0204$.

4. Energy Loss Expectancy Assuming a Straight Line Load Duration Curve

The straight line daily maximum load duration curve, used to calculate loss of load probabilities, now will be used to calculate energy loss expectancies. The energy loss with a given capacity outage depends on such factors as the nature of the load, the magnitude of the outage, and the method of voltage regulation. For the purpose of this discussion let it be assumed that with a capacity outage O_k in excess of reserve the load is decreased, say, by lowering the voltage, until equality between capacity available and load is re-established. On this basis, the energy loss with the outage O_k will be proportional to the area of the shaded triangle in Figure 8(A). The area of this triangle from equation 3 is:

$$\frac{1}{2} t_k (O_k - R_0) = (1-l) t_k^2 Lam$$

Let us assume that capacities are expressed in kilowatts. The energy loss expectancy in kilowatt-days during a period of T days, due to the outage O_k in the range (Case B),

Figure 9. Assumed energy loss caused by a capacity outage $O_k > R_0 + 2(1-l)Lam$

will be given by the following equation:

$$p_k T(1-l)t_k^2 Lam$$

$$= p_k T \frac{(O_k - R_0)^2}{4(1-l)Lam} = \frac{p_k T(O_k' - R_0')^2 Lam}{4(1-l)} \quad (9)$$

This expression is correct only if O_k is in the range (Case B), that is, if:

$$R_0 < O^k \leqslant R_0 + 2(1-l)Lam$$
$$R_0' < O_k' \leqslant R_0' + 2(1-l)$$

For values of O_k in the range (Case C) point "A," Figure 9, that is, in the range:

$$R_0 + 2(1-l)Lam < O_k \leqslant R_0 + Lam$$
$$R_0' + 2(1-l) < O_k' \leqslant 1 + R_0'$$

the expected kilowatt-days lost with the outage O_k will be proportional to the area $AA_1\ BB_1$ (Figure 9) or to:

$$\{O_k - R_0 - (1-l)Lam\}$$

The expected kilowatt-days loss will be:

$$p_k\{O_k - R_0 - (1-l)Lam\}T$$
$$= p_k\{O_k' - R_0' - 1 + l\}Lam\ T \quad (10)$$

The total energy loss expectancy in kilowatt-days will be given by the sum of: all terms as equation 9 for values of O_k' in Case B, plus all terms as equation 10 for values of O_k' in the range (Case B).

The energy loss expectancy in kilowatt-days per kilowatt of maximum load will thus be given by

$$T\{(1-l)\sum^{b} p_k l_k^2 + \sum^{c} p_k(O_k' - R_0' - 1 + l)\}$$
$$= T\left\{\frac{1}{4(1-l)}\sum^{b} p_k(O_k - R_0')^2 + \sum^{c} p_k(O_k' - R_0' - 1 + l)\right\} \quad (11)$$

Where, as previously stated, $\sum^{b}$ indicates that the summation is extended to all values of O_k' in the range $R_0' < O_k' \leqslant R_0' + 2(1-l)$ and $\sum^{c}$ indicates that the summation is extended to all values of O_k' in the range $R_0' + 2(1-l) < O_k' \leqslant 1 + R_0'$.

The energy loss expectancy in kilowatt-days per kilowatt of total capacity will be given by:

$$\frac{T}{1+R_0'}\left\{\frac{1}{4(1-l)}\sum^{b} p_k(O_k' - R_0')^2 + \sum^{c} p_k(O_k' - R_0' - 1 + l)\right\} \quad (12)$$

It will be noted that if $l = 1$, that is, if the daily maximum loads are assumed to be the same throughout the year, the range (Case B) disappears and equation 10 for the energy loss expectancy in kilowatt-days, with an outage O_k, becomes:

$$p_k T(O_k' - R_0')Lam \quad (10A)$$

Correspondingly, the energy loss expectancy in kilowatt-days per kilowatt of maximum load of equation 11 will reduce to:

$$T\{\sum p_k O_k' - R_0' \sum^{c} p_k\} \quad (11A)$$

It will be noted that both the energy loss expectancy in kilowatt-days per kilowatt of maximum load (equation 11), and in kilowatt-days per kilowatt of total capacity (equation 12), are proportional to the quantity:

$$(1-l)\sum^{b} p_k l_k^2 + \sum^{c} p_k(O_k' - R_0' - 1 + l) \quad (11\text{-}1A)$$

or its equivalent:

$$\frac{1}{4(1-l)}\sum^{b} p_k(O_k' - R_0')^2 + \sum^{c} p_k(O_k' - R_0' - 1 + l) \quad (11\text{-}1B)$$

Either one of these two expressions represents the energy loss expectancy expressed as a fraction of the possible maximum load energy, during a period T, that is, as a fraction of $T\ Lam$.

It will also be noted that equations 11-1A and 11-1B represent the sum of the products of the probabilities p_k by the shaded areas shown in Figures 8(B) and 9(B). If the energy loss expectancy as a fraction of the possible maximum load energy (equations 11-1A or 11-1B) is known, the energy loss expectancy per kilowatt of maximum load, during a period T, is obtained by multiplying these equations by T. Similarly, the energy loss expectancy, during T, per kilowatt of total capacity is obtained by multiplying equations 11-1A or 11-1B by $T/1+R_0'$.

5. Energy Loss Expectancy Assuming a Straight Line Load Duration Curve and All Units Similar and of the Same Capacity

Let us assume again, as under section 2 of this Appendix, that the system has n units all of the same capacity C_1. In this case:

$$O_k' = \frac{k}{n}(1 + R_0')$$

where k is the number of units out causing the outage O_k. Equation 9 for the expected energy loss in kilowatt-days in the range (Case B) becomes:

$$\frac{T}{4(1-l)} p_k \left\{\frac{k}{n}(1+R_0') - R_0'\right\}^2 Lam =$$
$$\frac{T}{4(1-l)} p_k \left\{\frac{k}{n} - R_0'\left(1 - \frac{k}{n}\right)\right\}^2 Lam \quad (13)$$

applicable to all values of k in the range (Case B), that is, in the range:

$$\frac{nR_0'}{1+R'} < k \leqslant \left\{1 - \frac{2l-1}{1+R'}\right\}n$$

Equation 10 for the expected kilowatt-days loss in the range (Case C) becomes:

$$p_k T\left\{\frac{k}{n}(1+R_0') - R_0' - 1 + l\right\} Lam \quad (14)$$

applicable to all values of k in the range (Case C), that is, in the range:

$$\left\{1 - \frac{(2l-1)}{1+R_0'}\right\}n < k \leqslant n$$

The energy loss expectancy in kilowatt-days per kilowatt of maximum load during the period T will be given by the equivalent of equation 11, that is, by:

$$T\left[\frac{1}{4(l-1)}\sum^{b} p_k\left\{\frac{k}{n}(1+R_0') - R_0'\right\}^2 + \sum^{c} p_k\left\{\frac{k}{n}(1+R_0') - R_0' - 1 + l\right\}\right] \quad (15)$$

The energy loss expectancy in kilowatt-days per kilowatt of total capacity is obtained from equation 15 by dividing by $(1+R_0')$.

Again it will be noted that if $l = 1$, equation 15 reduces to:

$$T\sum^{c} p_k\left\{\frac{k}{n}(1+R_0') - R_0'\right\} \quad (15\text{-}1)$$

Evidently, the expressions for the energy loss expectancy as a fraction of the possible maximum load energy in this case, from equation 15, is given by:

$$\frac{1}{4(1-l)}\sum^{b} p_k\left\{\frac{k}{n}(1+R_0') - R_0'\right\}^2 + \sum^{c} p_k\left\{\frac{k}{n}(1+R_0') - R_0' - 1 + l\right\} \quad (15\text{-}2)$$

or by:

$$(1-l)\sum^{b} p_k l_k^2 + \sum^{c} p_k\left\{\frac{k}{n}(1+R_0') - R_0' - 1 + l\right\} \quad (15\text{-}3)$$

Discussion

C. W. Watchorn (Pennsylvania Water and Power Company, Baltimore, Md.): The author has presented a very interesting method for determining various characteristics related to the application of probability methods to power system problems, including the effect of load characteristics, which latter factor has been neglected too often in generalized papers presented on this subject. However, it is desired to emphasize the author's admonition that the pro-

posed simplified method of calculation should be used for practical purposes only to obtain quick preliminary answers to problems involving the determination of installed capacity requirements. This caution is being emphasized because there are probably very few systems for which the load duration characteristics approach a straight line sufficiently to be so represented and result in reasonably reliable answers; and also, because there are probably very few systems for which their units, boilers and turbines in combination and interconnected variously, may be reasonably represented as being of average size without distorting the answers too greatly to be considered as other than being merely preliminary.

As the author points out, probability methods provide a very powerful tool for the solution of problems involving the relative advantages of alternative facilities. However, such relative advantages cannot be determined, at the present time, with sufficient accuracy other than by means of the longer more accurate application of probability methods, particularly as related, in most cases, to at least the alternative installations.

The discussor agrees fully with the author's recommendation that the probability of loss of load is the most practical and significant measure of service reliability and that it should be used as the index therefor. However, the "shedding" of load that results from a voltage reduction is in itself a loss of load and certainly should be so treated, and considered for what it actually is, an emergency measure for the rationing of service, rather than treating it as capacity, which it definitely is not. In addition, the variability of the general load level or the "load forecasting error" is a necessary factor in the rational determination of the level of service reliability. Consideration of the effect of these two elements in the evaluation of system capacity requirements leads to the conclusion that the level of service reliability of a loss of load expectancy of in the order of at the average rate of one day in ten years in both reasonable and adequate. The discussor has already so recommended or indicated on several occasions.[1,2,3]

3. THE DETERMINATION AND ALLOCATION OF THE CAPACITY BENEFITS RESULTING FROM INTERCONNECTING TWO OR MORE GENERATING SYSTEMS, C. W. Watchorn. *AIEE Transactions*, volume 69, part II, 1950, pages 1180–86.

G. Calabrese: I agree with Mr. Watchorn that the lowering of the voltage in order to reduce the load is an emergency measure. For this reason, it should not be used too often. How often it can and should be used depends on the type of service rendered and the composition of the system.

I also am in agreement with Mr. Watchorn's statement that the load forecasting error should be taken into consideration in determining the level of service reliability of a system.

Mr. Watchorn states that there are few systems for which the daily maximum load duration curve approaches a straight line. While this is undoubtedly true, I believe that in most cases it should be possible to replace the actual curve with a straight line, particularly if this is drawn to fit the portion of the actual curve corresponding to the higher loads, the most significant from the standpoint of the problem in hand. In extreme cases, when this is not considered satisfactory, the actual curve can be replaced with segments of straight lines.

Mr. Watchorn suggests a loss of load expectancy of one day in ten years. He does not state whether this level should be before or after voltage reduction.

Before closing this discussion, mention should be made of another point, namely, how often can loss of load be expected to occur? In other words, what is the expected frequency of loss of load expressed in terms of one loss of load occurrence every so many years. To the probability of loss of load, discussed in the paper, corresponds an expectancy of loss of load of one day every so many years. This expectancy, however, represents an average value which may obtain as a result of a large number of short loss of load occurrences or through a small number of long ones. The loss of load expectancy yields no information in this respect excepting that, on the average, loss of load will occur one day every so many years, or D days per year, in general D being a fraction of one day.

In order to answer the above question relative to the expected frequency of occurrence of loss of load, it is necessary to introduce the concept of continuance probabilities for simultaneous outages of units. Briefly, these are the probabilities that outages involving simultaneously a given number of units, say k, should last 1, 2, or 3 days once they have occurred. From past records, continuance probabilities for outages of k units are calculated as follows: let N_k be the total number of k-unit outages that have occurred in a past period. Of these N_k outages $n_{k1}, n_{k2}, n_{k3}, \ldots\ldots$, have lasted respectively 1, 2, 3, . . . days. From these recorded values, the continuance probabilities $\pi_{k1}, \pi_{k2}, \pi_{k3}, \ldots\ldots$ are now calculated.

$\pi_{k1} = \dfrac{n_{k1}}{N_k}$ = continuance probability that a k-unit outage shall last 1 day once it has occurred.

$\pi_{k2} = \dfrac{n_{k2}}{N_k}$ = continuance probability that a k-unit outage shall last 2 days once it has occurred.

Let $d_k = n_{k1} + 2n_{k2} + 3n_{k3} + \ldots\ldots$ be the total number of k-unit outage days involved. It is easily seen that

$$n_{k1} = \frac{\pi_{k1} d_k}{\pi_{k1} + 2\pi_{k2} + 3\pi_{k3} + \ldots}$$

$$n_{k2} = \frac{\pi_{k2} d_k}{\pi_{k1} + 2\pi_{k2} + 3\pi_{k3} + \ldots} \qquad (1)$$

that is, once the continuance probabilities for k-unit outages are obtained from past records, the number of k-unit outages lasting respectively 1, 2, 3 . . . . days, that can be expected to occur during a reasonably long period, can be calculated if the expected total number of k-unit outage days is known.

The continuance probabilities $\pi_{k1}, \pi_{k2} \ldots\ldots$ should be calculated for as many values of k as necessary and should be checked for stability, following the same general method outlined in reference 2 of the paper.

In order to determine the expected frequency of loss of load from the expected number of D days of loss of load, it is first necessary to determine the number of units k of the outages causing loss of load, for instance as shown in column 2 of the lower part of Table VI of reference 2. In this particular case, it is seen that loss of load is caused almost entirely by 3-unit outages. In the more general case, loss of load will be caused by outages of 1, 2, 3 . . . . units. In such a case, a complete analysis would require the fractionalization of D into portions $D_1, D_2, D_3 \ldots\ldots D_k \ldots\ldots$ according to the number of units involved. For each class of outages of k-units, the number of outages $n_{k1}, n_{k2}, \ldots\ldots$, lasting 1, 2 . . . . days, respectively, that may be expected during a sufficiently long period of years T, may now be calculated by replacing d_k with TD_k in equation 1 above. Sufficiency of the length of T for each value of k should be determined by the number of k-unit outage days necessary to obtain stable values of the continuance probabilities $\pi_{k1}, \pi_{k2}, \ldots\ldots$

Values of continuance probabilities for boilers and turbines, disregarding the number of units out simultaneously, may be obtained from Figures 5, 6, 7, and 8 of reference 1 of the paper.

In the particular case of Table VI reference 2, the calculated loss of load probability is 0.00162 corresponding to 1 day every 6,200 days. Since loss of load is caused almost exclusively by 3-unit outages, in order to obtain the expected frequency of loss of load it would be necessary to have a continuance probability for 3-unit outages. Lacking this information, for the sake of discussion let it be assumed that the average duration of a unit outage is four days. If it is assumed that this figure is applicable to 3-unit outages, the expected frequency of loss of load would be once every 24,800 days.

Report of the Board of Directors

THE BOARD OF DIRECTORS of the American Institute of Electrical Engineers presents to the membership its 66th annual report, covering the fiscal year ending April 30, 1950. It contains a brief summary of the principal activities of the Institute during the year, a general balance sheet showing the financial condition of the Institute at the close of the fiscal year, a statement of cash receipts and disbursements, and a schedule of securities owned. Much additional information regarding the activities appeared in various issues of *Electrical Engineering*.

BOARD OF DIRECTORS' MEETINGS

Five meetings of the Board of Directors were held during the year, two in New York, N.Y., one in Swampscott, Mass., one in Cincinnati, Ohio, and one in Providence, R.I.

Information regarding many of the more important matters which were considered by the Board of Directors appeared in various issues of *Electrical Engineering*.

INSTITUTE POLICY

As a result of many discussions, in meetings of the Board of Directors and other groups, regarding proposals that the Institute participate in various activities of the broader, nontechnical types, a resolution intended to define the Institute as "strictly a scientific and educational organization" was discussed for several hours in the April 1949 meeting of the Board of Directors.

The resolution was referred to a special committee whose assignment was to stimulate discussion and consideration of the subject both in the next meeting of the Section Delegates and in the Sections, and to report to the Board of Directors not later than the time of the Board meeting at the 1950 Winter General Meeting.

All Sections were requested to urge their members to vote upon the following two courses:

1. I favor adhering to the technical field.

2. I favor expanding in nontechnical field with increased dues.

The vote was 7,245 in favor of proposition 1, and 2,063 in favor of proposition 2.

The special committee presented to the Board of Directors, on February 2, the following proposals of policy:

1. The Board of Directors will work continually for the unification of the profession.

2. The Board of Directors recognizes the fact that the Institute finds its chief reason for existence in the technical field.

3. The Board of Directors will handle questions on nontechnical affairs as necessary and as they arise, on an emergency basis until through unification they can be handled on a general professional basis.

The Board of Directors approved the recommendation that these three proposals be published in *Electrical Engineering* for March, with a report on the vote conducted by the Sections, and a return postal card, on which each member was requested to approve or disapprove each of the three proposals.

At the meeting of the Board of Directors in Providence, on April 27, the following results, to April 14, were reported:

Proposal	Number 1	Number 2	Number 3
Approved	3,391	3,386	3,331
Disapproved	252	290	312

The time for conclusion of the ballot was extended to May 15.

ANNUAL MEETING

The 66th annual business meeting of the Institute was held in Swampscott, Mass., June 22, 1949. The annual report of the Board of Directors for the fiscal year which ended April 30, 1949, was presented in abstract by Secretary H. H. Henline, who also presented a report of the Committee of Tellers on the vote of the membership on the election of officers whose terms were to begin on August 1, 1949. In the absence of Treasurer W. I. Slichter, his report on Institute finances was presented by Secretary Henline. President-elect James F. Fairman was introduced, and responded with a brief address.

The Lamme Medal for 1948 was presented to Dr. V. K. Zworykin, Vice-President and Technical Consultant, Radio Corporation of America Laboratories Division, Princeton, N. J.

An address, "The Expanding Horizons in Engineering Education," was given by William F. Ryan, Engineering Manager, Stone and Webster Engineering Corporation. Preceding his address, Mr. Ryan, as Vice-President of the Northeastern Section of the National Society of Professional Engineers, presented to Mr. Fairman a tribute of esteem from his friends in many parts of the United States, a richly bound volume of congratulatory letters from officers of the NSPE and the presidents of many of the state societies.

The last item on the program was an inspiring address entitled "Open Doors," by President Everett S. Lee.

GENERAL MEETINGS

Four general meetings were held during the year, and a brief report on each follows:

Summer General Meeting. The 65th Summer General Meeting was held in Swampscott, Mass., June 20–24, 1949, with a registration of 1,650. The program included 30 technical sessions and conferences, the official annual business meeting of the Institute, 50 committee meetings, Section Delegates conferences, and a meeting of the Board of Directors. Social and entertainment features included a barn-dance, President's reception and banquet, New England entertainment, and special events for the ladies. Various types of inspection trips were available.

Pacific General Meeting. The Pacific General Meeting was held in San Francisco, Calif., August 23–26, 1949, with a registration of 878. There were a general session ad-

dressed by W. C. Mullendore, President, Southern California Edison Company, Ltd.; a luncheon meeting addressed by President Fairman; 15 technical sessions and conferences; two student sessions; a meeting of District, Section, and national officers, and Branch Counselors; a meeting of Branch officers and Counselors; a banquet; a student dinner and meeting; inspection trips; golf tournament; and ladies' events.

Fall General Meeting. The third Fall General Meeting was held in Cincinnati, Ohio, October 17–21, 1949. The registration was 1,045. The program included a general session with three addresses, by President Fairman, Dr. Raymond Walters, President of the University of Cincinnati, and Robert S. Peare, Vice-President in charge of Public Relations, General Electric Company; 31 technical sessions and conferences; a luncheon and session at the University of Cincinnati for discussion of intersociety relationships in Cincinnati; inspection trips; a dinner-dance; and an extensive ladies' program. Also, a meeting of the Board of Directors, a District Executive Committee meeting, and about 40 committee meetings were held.

Winter General Meeting. The Winter General Meeting was held in the Hotel Statler, New York, N. Y., January 30–February 3, 1950, with a registration of 3,213, and a record program of 58 technical sessions and conferences, and presentation of 243 papers. In a general session, addresses were given by Harold E. Stassen, President, University of Pennsylvania, and Sir Ernest Benn of London, England (in absentia), and an Honorary Member certificate was presented to Dr. Vannevar Bush, President, Carnegie Institution of Washington. Approximately 90 meetings of technical and administrative committees and a meeting of the Board of Directors were held. In addition, there were inspection trips, a smoker, a dinner-dance, and ladies' entertainment events.

DISTRICT MEETING

North Eastern District Meeting. A North Eastern District Meeting was held in Providence, R.I., April 26–28, 1950, with headquarters at the Sheraton-Biltmore Hotel. The registration was 502. The meeting consisted of eight technical sessions, two student technical sessions, a luncheon meeting of Branch Chairmen and Counselors, inspection trips, two banquets, and ladies' events. A meeting of the Board of Directors, a conference of Vice-Presidents, and a meeting of the District Executive Committee were held.

SPECIAL TECHNICAL CONFERENCES

"Special Technical Conferences" were inaugurated in 1948, and have proved so successful that the number being planned and held has increased rapidly. The conferences are intended to be national in interest, technical in character, and concentrated as to subject matter toward one particular industry or objective. This type of meeting is designed to explore thoroughly a limited field and to afford specialists in that field an opportunity to discuss mutual technical problems. The conferences may be defined as a program of panel discussions, technical papers, or exhibits under the auspices of a national technical committee, in co-operation with an AIEE local Section, which might act as host to the conference. Operating under the policy and procedure which has been set up, the following conferences were held during the past fiscal year.

Conferences on the Textile Industry. Electrical engineering problems in the textile industry was the subject of two technical conferences held in May 1949. The first was in Boston, Mass., May 3, and was sponsored by the Textile Industry Subcommittee of the Committee on General Industry Applications, in co-operation with the Boston Section. Seven papers and two moving pictures were presented during the two sessions of the conference. Subjects covered by the papers ranged from cloth production in the loom to cloth finishing. The attendance was 65. Approximately 95 persons attended the conference at the Georgia Institute of Technology, Atlanta, Ga., May 27–28, which was sponsored also by the Textile Industry Subcommittee, in co-operation with the Engineering Extension Division of the Georgia Institute of Technology and the Georgia Section. Among the many interesting subjects discussed were electric equipment for textile machines, loom research, fire hazards, electrostatic air cleaning, and so forth. Proceedings of these conferences have not been published, but some digests of the papers presented appear in the September 1949 issue of *Electrical Engineering*.

Conference on Electric Equipment for Materials Handling Bridges was held in Cleveland, Ohio, May 13, 1949, sponsored by the Materials Handling Subcommittee of the Committee on General Industry Applications and the Cleveland Section. The topic of "Electric Equipment for Materials Handling Bridges" was considered in several prepared papers, followed by round-table discussion. The attendance was 85.

Conference on Electronic Instrumentation in Medicine and Nucleonics was held in New York, N. Y., October 31, November 1–2, 1949, sponsored jointly by committees of AIEE and the Institute of Radio Engineers. The sponsoring committees included:

For AIEE: Committee on Nucleonics, Committee on Electronics, Committee on Instruments and Measurements, Joint Subcommittee on Nucleonic Instrumentation, Joint Subcommittee on Electronic Aids to Medicine

For IRE: Professional Group on Nuclear Science, Nuclear Studies Committee

The first day of the 3-day gathering was devoted to the nonnucleonic phases of electronics in medicine. The second day's sessions dealt with nucleonics in medicine. A round-table discussion on "Evaluation of Radiation Hazards" was held during the evening of the second day. The last day's sessions were concerned with nucleonic developments in industry and government. Six sessions provided for the presentation of 21 papers, in addition to the discussions and address which were a part of the round-table discussion panel held in the evening. More than 800 persons attended the conference, and an interesting and very popular feature was an exhibit of commercially available nucleonic equipment. Complete proceedings of the conference have been printed in book form and are available at a price of $3.50.

Conference on Electric Welding was held at the Rackham Memorial Building, Detroit, Mich., April 5–7, 1950, sponsored by the Committee on Electric Welding, in co-operation with the American Welding Society and the Industrial Electrical Engineers' Society in Detroit. The conference, which was the second Welding Conference, provided an opportunity for the presentation in six sessions of 24 papers on arc and resistance welding. Two of the evenings were devoted to demonstrations of electric welding techniques and equipment. These included several inert gas welding processes, stud welding, submerged arc welding, a 3-phase rectifier-type d-c arc welder, portable gun welding, and resistance welding controls. The total attendance at the conference was 420. The papers and discussions will be published in a bound volume at a price of $3.50.

Conference on Electric Space Heating was held at the Rogue Valley Country Club, Medford, Oreg., on April 12, 1950, sponsored by the Committee on Domestic and Commercial Applications. This was a 1-day meeting with a general session in the evening. No prepared papers were presented, but for those wishing to present technical data there was a preliminary meeting in the afternoon to make arrangements so that everyone who was interested could be heard. Subjects discussed were domestic heating, domestic load control, and heat pump performance. The attendance was 34.

The Second Southern Conference on Electrical Application for the Textile Industry was held at the Georgia Institute of Technology, Atlanta, Ga., April 13–14, 1950, sponsored by the AIEE Textile Industry Subcommittee of the Committee on General Industry Applications, and the Georgia Institute of Technology. Three sessions at this conference provided for the presentation of nine papers, which were arranged to keep the persons in the textile field informed on new scientific and engineering developments which are in progress. The subjects covered packaged drives, power wiring, lighting, electronics, and air conditioning. The attendance was 210. A Conference on Textiles for New England was incorporated as a session, on April 27, of the North Eastern District Meeting, which was held in Providence, R. I. Four papers were presented at this session, and an inspection was made on the same day of the Owens-Corning Fiberglas Corporation plant at Ashton, R. I. The attendance at the session was 126.

Power Conference. The Pittsburgh Section was host to a 2-day Power Conference in Pittsburgh, Pa., April 19–20, 1950, sponsored by the Committees on Industrial Power Systems, Power Generation, and System Engineering. A well diversified program was planned to attract as large an attendance as possible and ensure active discussion. This resulted in the presentation of 18 papers in four sessions, and all proved of practical interest to central-station and industrial plant designers and operators. This was the first technical conference to be sponsored by a committee within the Power Group, but was most successful, with an attendance of 300. Published proceedings of this conference will be available at a price of $2.50.

General Committees

BOARD OF EXAMINERS

The Board of Examiners, for the first time in many years, has been able to conduct its business at the regularly scheduled monthly meetings, without having to hold extra sessions.

Students		
Recommended for enrollment as Students		7,733
Total		12,764

Statistics relating to the number of cases handled by the Board are given in Table I. The current total, excluding "enrolled Students," is four per cent less than for 1948–49. This is largely due to a decrease in Associate applications, which have dropped seven per cent. Student enrollments have dropped 12 per cent. The decrease in Associate applications and in Students' enrollments was not unexpected, both being largely affected by enrollments in colleges under the "GI Bill o Rights."

COMMITTEE ON CODE OF PRINCIPLES OF PROFESSIONAL CONDUCT

Two matters were carried over from the preceding year. The first was the case of the Southwestern Power Administration in advertising for competitive bids for professional electrical engineering services. Formally, that matter was closed two years ago with this committee's report to the Board of Directors (in which it was found that there had been no violation of the Canons of Ethics of the Engineers' Council for Professional Development, or of the Institute Code. The committee's belief was reported that such practices should not be encouraged and that necessity for them by such a governmental agency should be removed by legislative or executive action). This matter has been before the committee this year only through copies received of correspondence of the Institute President and the Southwestern Power Authority aimed to find out if the prior technical difficulties had been removed. However, the question of competitive bidding is a live matter, being discussed by regional engineering associations, and this subject could well be continued by this committee.

The second matter carried over was the projected "Statement of Principles of Professional Conduct" combining the Canons of Ethics of the Engineers' Council for Professional Development, verbatim, with certain rules of practice contained in the old Code of the Institute. It was thought that a draft had been agreed upon for submission when a new matter arose which led to a recommendation to change the Institute Bylaws. That change suggested a change or addition to the pending "Statement of Principles" which has held up the presentation. It is expected that this whole matter can be closed during the current administrative year.

One new matter arose during the year. A case was reported to the Institute, and referred to the committee, where an electrical contractor who was an Associate did business under a corporation name, and carried insignia of the Institute on corporation letterhead and advertising. The committee believed that the Associate in question had merely not appreciated the distinction between the Institute and contractors' associations by which such practices are approved. It was emphasized that membership in the Institute is a wholly personal and professional matter, that insignia are to be displayed only on Institute letters and publications, except of course in the wearing of membership badges and use of personal membership statements on stationary, and so forth. A change in the Bylaws clarifying this whole situation was recommended to the Directors and adopted by them. It now rests with the Committee on Constitution and Bylaws. A corresponding addition to the projected "Statement of Principles of Professional Conduct" is being considered.

COMMITTEE ON CONSTITUTION AND BYLAWS

This committee submitted certain recommendations to the Board of Directors in advance of three meetings, and the Bylaws were amended as outlined in the following.

June 23, 1949. A change was made in Section 19 to clarify the time of notification of Members for Life.

A change was made in Section 26 regarding the general meetings, identifying them as Winter General Meeting, Summer General Meeting, Pacific General Meeting, and Fall General Meeting.

Section 64 was amended to include certain new committees and rearrangement of the technical committees.

October 20, 1949. Sections 6 and 7 were amended so as not to require the publication in *Electrical Engineering* of the names of applicants for admission to the Institute as Associates.

February 2, 1950. Sections 10 and 17 were amended to clarify the requirements of notice regarding members in arrears.

The printing on the annual dues bill and each of the quarterly notices sent to those remaining in arrears of Sections 16, 17, 18, and 12 of the Bylaws, covering the billing of annual dues, delinquencies, and reinstatement, is now required by Section 17.

COMMITTEE ON EDUCATION

The committee sponsored three conference sessions as reported in the following paragraphs.

At the Summer General Meeting, the conference theme "Accrediting of Engineering Curricula" was dealt with in two talks, one on the accrediting program from the point of view of those administrating it, and the other on what the visitor sees. The purpose of the session was to provide an opportunity for Institute members to become acquainted with what the committee thinks is a powerful, but not very well known, influence in electrical engineering education.

At the Fall General Meeting, the conference subject was "Problem and Thesis Subjects From Industry." In three excellent papers presented by six engineers in industry, typical problems were presented, by example, from the fields of application, design, and industrial electronics. Such problems are of value to the teacher and student especially in bringing the point of view of the classroom closer to that of industry.

At the Winter General Meeting, the theme was "Post-College Development of Engineers." The five papers, resulting from studies made by the ECPD Committee on Professional Training, covered the various aspects of the subject: the orientation and training of the young engineer in industry, his continued education, methods for appraising himself, professional registration, and integrating him into his community. These were the basis of a spirited discussion, and should be of particular significance to the Institute, whose life and growth are in a large measure dependent upon the quality and attitudes of the young men from whose ranks it recruits its new members.

Four of the five papers of the first two conferences were published in *Electrical Engineering*, and a summary of the third conference is in prospect for publication.

The conference scheduled for the Summer and Pacific General Meeting deals with the planning of new electrical engineering laboratory facilities for colleges. Quite a number of new laboratories have been built in recent years, and others are in the planning stages; hence, the conference should serve as a medium for the exchange of ideas.

Future work of the committee is expected to include studies through subcommittees, of the following subjects: objectives of the electrical engineering curriculum, graduate programs, measuring the effectiveness of educational programs, and accrediting. It is expected that these topics will be the subjects of future conferences.

FINANCE COMMITTEE

For the budget year October 1, 1949, to September 30, 1950, the Board of Directors adopted a balanced budget, and the financial performance for the first six months of that period has been approximately in line with the budget provisions. Due to the fact that expenditures occur fairly evenly from month to month, but receipts are much greater after May 1 then they are prior to that time, it is necessary to engage in temporary transfers or borrowings during the later winter. This year is no exception, and $40,000 was transferred from the Reserve Capital Fund to the General Fund, which will be repaid from dues receipts after May 1.

The remedial factors mentioned in last year's report which are designed to ease the Institute's financial situation are in operation:

1. Increased advertising rates in *Electrical Engineering*.
2. Registration fees for general and District meetings.
3. More adequate price scales for Institute publications.
4. Excellent co-operation by committees responsible for sizable expenditures in the effort to live within budget limitations.

The results of these measures and others effective in the same direction were such as to remove the apparent immediate necessity for an increase in dues, so the Special Committee on Institute Dues was discharged with thanks.

It is recognized, however, that the financial picture can change radically with great speed, due both to substantial decreases in income

and to a sustained upward trend in expenditures, so the necessity for continued vigilance in financial matters is just as important now as it has been. So far, income is holding up very well, but items tending to enlarge the size of expenditures are constantly appearing. Publication costs, both for material and production, are still going up; appropriations to other organizations, maintained in part by the Institute, are increasing; a study has been made of the Institute traveling allowances, with the view of making them more adequately compensatory under present conditions; to mention only a few such influences.

The Reserve Capital Fund is the Institute's "anchor to windward," and it is available to permit the maintenance unimpaired of our present activities during any probable necessary period for the adjustment of our financial requirements to a new situation.

HEADQUARTERS COMMITTEE

The chief activity of this committee concerned the study and application of air-conditioning equipment for all office space at Headquarters. In accordance with a recommendation to the Board of Directors, a special grant was authorized and an order placed for the installation of 21 units. At the time of this report, the installation is practically complete, and it is expected that considerable increase in office efficiency will result during the summer months.

The committee also continued the program of modernization of lighting fixtures with the installation of additional fluorescent units in several offices. Replacement of the fixtures in the Board of Directors' room with units of more modern design is under consideration, and will be accomplished in the near future.

The table in the Board of Directors Room was polished and provided with a new felt cover.

Other matters on the agenda concern the cleaning of rugs, shampooing of upholstered furniture, addition of identifying lettering on office doors, and a new bulletin board for the reception area.

COMMITTEE ON MANAGEMENT

The major question before the Committee on Management during the year was to decide whether such an activity fitted into the scope of the AIEE. To this end, a very complete questionnaire was circulated to the members of the committee, and a meeting was held in New York during the Winter General Meeting. As a result of this work, the committee had a part-session at the North Eastern District Meeting, and is organizing a session for the 1951 Winter General Meeting, with a view to finding out the interest of the membership in such meetings.

It is believed that, as a result of these two sessions, the committee will be in a much better position to judge whether or not management should be a part of AIEE activities.

MEMBERSHIP COMMITTEE

Membership in the Institute increased by 3,407 members in the year ending April 30, 1949. This was a 40-per cent greater growth than 1949, and the largest on record. Previous to this period, the maximum annual increase had been 2,018 in 1946. Table II of membership statistics shows the nature of the changes in membership during the year. The substantial growth reflects both the heavy graduation of electrical engineering students from the universities and the stepped-up activity of the Membership Committee itself. Of the total applications amounting to 6,450 received during the year, 4,033 were from students, and 2,417 from others. The total applications received include those of graduates who applied last June and who were not elected to Associate membership until April 1950. There were a total of 3,347 former Student members approved at this meeting. Apparently the new plan has stimulated interest among the graduating Student members.

A further stimulation to transfer has come from the accelerated activity of the Membership Committees among the college graduates during their first year out of school.

Members in arrears for dues for the fiscal year ending April 30, 1950, reached a total of 1,510 compared with 1,376 last year. This represents a delinquency of 0.442 per cent compared with 0.448 per cent a year ago, showing slight improvement. During the year, there were 682 members dropped compared with 685 for the previous year. On the other hand, the number resigning increased from 277 to 343, but this loss of membership is to be expected due to the larger number of members.

During the year, the Membership Committee completed work on a revised "Membership Information" pamphlet, under the subcommittee chairmanship of Walter Bloomquist. The new booklet was designed for wide distribution. It gives short statements on the value of membership in the Institute and eligibility requirements. It is thought that this will be a valuable tool for Membership Committees in the future.

The Subcommittee on Survey of Student Branches under the chairmanship of J. C. Woods, co-operating with the Committee on Student Branches, submitted its final report. The purpose of this committee was to organize and undertake a survey of Student Branch membership as a function of maximum potential membership at each school, and to investigate the policies surrounding and reasons for the acceptance of local members. Since

1904	3,027	1926	18,158	1948	28,408
1905	3,460	1927	18,344	1949	30,791
1906	3,870	1928	18,265	1950	34,198

the Student members are the most important source of new Institute members, it was thought that maximum effort should be exerted in this field. It has been recommended that the Committee on Student Branches take an active interest in this subject and develop a uniform method of membership practices in the universities, which will stimulate student activities.

The committee wishes to commend the excellent co-operation and sincere efforts of the Section Membership Chairmen throughout the year. The increase in applications from other than Student members attests to the fact that they have been extremely active. The District Vice-Chairmen have increased their contact with the local Section Chairmen substantially, and this new method is also proving highly effective. The tremendous growth of the Institute indicates that sights should be raised above those of the past and serious consideration given to the day not far ahead when a membership of 50,000 will be reached.

COMMITTEE ON PLANNING AND CO-ORDINATION

The committee held its usual number of meetings during the year, each preceding by a few days a Board of Directors meeting.

Scheduling of Future Meetings. The future general and District meetings of the Institute have been scheduled up to and including 1952. The attempt to obtain spacing between District meetings, even though these are held in widely separated parts of the United States, has been continued. Consideration was given to respacing the general meetings with particular attention to the Fall and Winter General Meetings. After thorough study, however, the committee was convinced that the present procedure provides the best general schedule. With the assistance of the Technical Program Committee, an attempt is being made to swing papers from both the Summer and Winter General Meetings into the Fall General Meeting. A growing number of technical conferences is being arranged for and co-ordinated through the proper technical committees.

Registration Fees. The matter of registration fees to be charged at general and District meetings has been subjected to continuing review. There has been general acceptance of the present method and no change is contemplated.

Technical Activities. With the recommendation for the establishment of the Technical Advisory Committee, the Technical Activities Subcommittee, active since Dr. Wickenden's administration, will be discestablished.

Ex Officio Assignments. After a study of the large number of ex officio assignments which have grown up under the existing Bylaws, the committee has recommended the dropping of all such assignments in the Bylaws. This will tend to relieve the burden on some of the key committee positions and to distribute in more balanced fashion and to a greater number of members the administrative work of the Institute. As an instance, the Committee on Award of Institute Prizes, whose chairman in the past had been the Chairman of the Technical Program Committee, has been divorced completely from this ex officio relationship, and in the coming year will operate with a group of members who, while appointed from the technical committees, are not rigidly held to an ex officio group. Many other similar simplifications are in the process of being made.

Changes in District Setup. The study of redistricting done by the committee four years ago was brought out and re-examined with a recommendation for no change in the immediate future.

Emblem. Various suggestions as to special emblems to recognize specific offices and for change in design of the present emblem were reviewed, with the recommendation that the emblem design and procedure remain as at present.

PUBLICATION COMMITTEE

The publication services of the Institute can be divided into five broad classifications: *Electrical Engineering, Transactions, Proceedings,* Advance Pamphlet Copies of papers to be presented at meetings, and Special Publications. Provision for these publications was made in the policy which became effective January 1, 1947. The number of pages of published material for the calendar year

1950 is shown in Table VII, together with the number of pages published in preceding years for ready comparison.

Electrical Engineering. Efforts have been made to keep the quality of publication on a high standard by not republishing material which has been published previously elsewhere. In Table VIII, a classification of articles in seven broad fields is presented. The tabulation shows a substantial increase in the number of general interest articles, as well as the number of communication articles. In the future, attempts will be made to increase the number of articles in the fields of industry and general applications to bring these fields more nearly in proportion to the interests of the members.

The practice of publishing a series of essays by well-known authorities, which present a statement of a problem one month, followed by the solution the succeeding month, has met with popular response. The activity has met with favor particularly in the field of education.

The circulation of *Electrical Engineering* has steadily increased with the growth in membership and number of Student members with an all-time high of 58,000 copies of the December issue and an average circulation of 53,825 copies for the year 1949, as compared with 47,800 copies for the year 1948.

Advertising. The number of pages of advertising is about the same as it was a year ago. By the end of the appropriation year, the gross revenue and the net revenue will be larger than they were for the preceding year because all contracts will have been in effect for the entire year at the increased rates which became effective February 1, 1948.

Transactions. Volume 68 of the 1949 *Transactions* has been made available in two parts. Part 1, which contains the papers presented during the first half of the year consisting of 800 pages, was made available for distribution November 15. Part 2, including the papers which were presented during the last half of the year, the Board of Directors' Report, and a complete index comprising 644 pages, was made available for distribution on March 27. This is a month and two months sooner than the corresponding parts were made available for the previous year.

AIEE Proceedings. During the year there has been a substantial increase in the number of *Proceedings* papers ordered and distributed. A total of 7,709 orders were received as compared with 6,295 orders during the preceding year. This represents a $22^1/_2$-per cent increase in the total number of orders received and represents a distribution of 55,826 copies of papers. When it is considered that there were 202 papers available this year as compared with 247 during the preceding year, the percentage increase on the basis of the number of orders received per paper is even greater, or 47.6-per cent. The increase is attributed to the publication of a reference on the cover of *Electrical Engineering* to the location of the *Proceedings* order form in the advertising section. Most of the copies ordered are for the 10-per cent free allowance and the total receipts were $945.70 as compared with $644.00 during the preceding year.

The *Proceedings* are an interim service to members and Student members only who fill out order forms published in *Electrical Engineering* every few months. In the case of members, there is a 10-per cent free allowance; but in the case of Student members, there is no free allowance.

Table VII. Numbers of Pages of Published Material

Year	Electrical Engineering: Technical Articles	Electrical Engineering: News	Electrical Engineering: Transactions Sections	Transactions Only: Technical Papers	Transactions Only: Discussions	Transactions Only: Total
1941	337	281	600	542	268	2,028
1944	246	214	738	493	231	1,922
1945	255	225	736	121	143	1,480
1946	285	315	832	254	120	1,806
1947	806	474		1,600*	153*	3,033
1948	832	395		1,643†	172†	3,042
1949	796	320		1,275‡	167‡	2,558

* Preprinted in 227 sections of *AIEE Proceedings*, except for a 17-page technical paper in *Electrical Engineering*.

† Preprinted in 247 sections of *AIEE Proceedings* requiring a total of 2,090 pages.

‡ Preprinted in 202 sections of *AIEE Proceedings* requiring a total of 1,795 pages.

Table VIII. Classification of Articles in Electrical Engineering in Seven Broad Fields

	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.	Jan.	Feb.	Mar.	April	Total
General interest	1		1	2	2	3	2	2	1	2	4	2	22
Educational	1	1	1	1			1	1	1	1	1		9
Science and electronics	2	2	1	1	1	1	4	3	3	2	2	3	25
Communication	3	2	1	1	2	1	1	2		3	3	1	20
Power	2	2	1	2	2	3	3	1	2	3	3	4	28
Industry			3	1	1		1	1		1		2	10
General applications		1	2			1	1						5
	9	8	10	8	8	9	13	10	7	12	13	12	119

Special Publications. During the year, the following ten special publications have been made available and ten more are in prospect. The editorial staff has been enlarged to handle the increased number of these publications. They fill a specialized need and some are used for educational purposes. The special publications are on a self-supporting basis and they are made available to members at cost and in general to nonmembers at double cost through order forms published in *Electrical Engineering* from time to time. In the future, sale prices are to include the cost of editorial time.

1. Electric Arc Resistance Welding* (5/49).
2. Mathematics for Engineers (7/49).
3. Industrial Application of Electron Tubes* (9/49).
4. Interior Wiring Design for Commercial Buildings (10/49).
5. Automatic Contouring Control of Machine Tools (10/49).
6. Electrical Engineering Problems in the Rubber and Plastics Industries* (12/49).
7. Bibliography on Rotating Machinery (1/50).
8. Symposium on Electrical Properties of Semiconductors and the Transistor (1/50).
9. Bibliography on Electronic Power Converters (1/50).
10. Electronic Instrumentation in Nucleonics and Medicine* (4/50).

Advance Copies of Papers. The practice of making technical papers approved for presentation at meetings available in advance copy pamphlet form by a photolithographic process has been continued. The few of the papers which are not of permanent record value have been made available as miscellaneous papers known as (ACO) "Advance Copy Only." Advance copies of papers are intended primarily for discussion purposes with a free allowance of ten copies to authors and 50 copies to the sponsoring committee. The other copies are sold to members at a price of 30 cents each and to nonmembers at a price of 60 cents each. The activity is nearly on a self-supporting basis.

* AIEE Conference Report.

Cumulative Index, 1939–1949. Work is well under way on an 11-year cumulative index to the *Transactions*, thus completing the series of cumulative indexes to the *Transactions* since the founding of the Institute in 1884. The index is expected to be made available the latter part of June or early in the summer and it is estimated that it will sell at a price of $2.50 per copy.

Special Subcommittee. A Special Subcommittee has been appointed to consider publication policy in relation to the following suggestions received: The view was expressed that the present publication policy was inadequate to command the loyalty of young but brilliant men electrically trained who are doing frontier work in the electrical sciences in the newer phases of electrical engineering closely related to electronics. Another suggestion received was to the effect that the publication policy to publish 1-page digests of all technical papers in *Electrical Engineering* should be abandoned in favor of briefer abstracts of eight or ten lines, to permit more space to be devoted to the treatment of papers in full. These suggestions are being given thorough consideration and study.

COMMITTEE ON PUBLIC RELATIONS

This year has marked the beginning of a strengthened public relations program for the Institute. Following authorization by the Board of Directors of a modest budget for this purpose, the committee on September 1, 1949, engaged the services of Raymond C.

Mayer to serve as Public Relations Counsel. The Mayer organization is thoroughly familiar with Institute affairs, having publicized several Winter General Meetings in New York and prepared the "publicity kit" which was distributed to Section officers in the spring of 1949, and has since been augmented.

It is the aim of the committee and of its counsel to treat the Institute's public relations as a continuing and integrated program rather than as a series of sporadic efforts centered about the Winter General Meeting. So far as is possible, all important Institute meetings are being given complete news coverage on papers, awards, and other items that show any promise of interesting the general public.

For the Fall General Meeting, 72 papers were examined, and 19 press releases issued. The releases were prepared by the Mayer organization and issued in the Cincinnati area through the AIEE publicity chairman. Releases to national periodicals, press services, trade papers, and others are sent out directly from New York. The same procedure was followed for the North Eastern District Meeting and will be continued for the meetings in Pasadena, Baltimore, Oklahoma City, and elsewhere. Institute technical conferences and a number of the Section meetings are also being systematically publicized.

The publicity kit, giving a large amount of instruction and sample material for local use, supplied to Section Chairmen and publicity officers, has been favorably received. New material for the kit is being distributed on a continuing basis; it includes sample radio programs and general instructions for conducting radio and television programs.

At the Winter General Meeting, a fully equipped and well staffed press room was maintained at the Hotel Statler. A large number of newspaper writers and photographers were given assistance, and 54 releases on technical papers and special addresses and awards were issued. At the suggestion of the committee, the general session was held on the opening day. This aroused an immediate interest in the meeting on the part of newspaper men, an interest which continued throughout the week. The committee also assisted in the preparation of a television exhibit which formed an attractive feature of the meeting.

Assistance has been given to several Sections and to other Institute groups confronted with special problems in their local fields or dealing with special areas of work.

In general the year's activities represent considerable progress in carrying forward the public relations policy established by the Board of Directors. The committee thinks this is on the right track and further progress is to be expected. This program will aid materially in promoting adequate recognition of the work of the Institute and of engineers.

COMMITTEE ON REGISTRATION OF ENGINEERS

The committee has continued its efforts to advise the AIEE membership on the problems of registration.

The committee held a meeting at the Winter General Meeting, with practically the entire membership in attendance.

Previously this committee had arranged for the publication of a paper entitled "Registered Professional Engineers," by R. W. Sorensen and A. H. Lovell. This paper appeared in the August 1949 issue of *Electrical Engineering*. This committee has advised the Student Branches and Sections that this paper is available at headquarters for their use, and has further suggested that it be used as a basis for discussion at local meetings.

It is planned to follow the Sorensen–Lovell paper with two other papers, each covering a particular phase of registration. These are to be published in *Electrical Engineering* in the near future. Reprints of these papers will also be made available at Headquarters.

At the request of the committee, the Board of Directors approved the plan of indicating in the Year Book the AIEE members who are registered professional engineers. This will start with the 1950 edition.

COMMITTEE ON RESEARCH

The Committee on Research sponsored jointly with the Committee on Basic Sciences a symposium on dielectrics. Seven speakers presented various phases of the subject very effectively. Attendance at each of the two sessions exceeded 200.

Plans for sponsoring a symposium on a new and interesting subject are now being formulated for the 1951 Winter General Meeting.

SECTIONS COMMITTEE

Section Activities. Two new Sections, Oak Ridge and Northeastern Michigan, were formed, and applications for two more, Sacramento and Saginaw Valley, are pending.

New Subsections were formed as follows: Eastern Shore, Maryland Section; Mobile-Pensacola, Alabama Section; Ridgway, Erie Section; St. Lawrence International, Syracuse Section; Savannah, Georgia Section; Tacoma, Seattle Section; West Michigan, Michigan Section.

The following additional Subsections are pending: Columbus, Ga.; Boise, Idaho; Alaska; Evansville, Ind.; Grand Rapids, Mich.; Sioux City, Iowa; Finley, Ohio; and Youngstown, Ohio.

Section, Subsection, and membership development has been very active and healthy, as noted above and as shown in Table IX.

The Vancouver Section which has been a part of District 10 has been transferred to District 9, but provision has been made for a yearly visit by the Vice-President of District 10.

Prize Award Rules. A revision of the Institute Prize Paper Rules was prepared by a subcommittee of the Sections Committee, and approved by the Board of Directors, and is now in effect.

Meetings of the Sections Committee. A meeting of the Sections Committee was held during the Winter General Meeting. Two meetings are scheduled for Section delegates during the Summer and Pacific General Meeting.

Section Finances. A subcommittee of the Sections Committee, under the chairmanship of G. W. Bower, has made a progress report on its survey and study of the problem of Section finances for the next 5-year period, which indicates that in general the Sections are getting along fairly well with their present allotments, and should be able to get along for the next few years without an increase. This subcommittee will continue the study and co-operate with the Sections in an endeavor to make this possible.

Survey of Membership Opinion on Institute Policies. At the request of M. D. Hooven, Chairman of a special committee appointed by the Board of Directors to obtain the opinion of the members on the Institute's future policy, a very thorough survey was conducted by the Sections. On the basis of some 9,000 votes, the Board of Directors came to the following conclusions:

1. To work continually for the unification of the profession.
2. To recognize the fact that the Institute finds its chief reason for existence in the technical field.
3. To handle questions on nontechnical affairs as necessary, and as they arise, on an emergency basis, until through unification they can be handled on a general professional basis.

Special Activities. A subcommittee has been appointed to revise the present suggested Bylaws for Sections, not only to bring them up to date to incorporate operation of Subsections, but also to emphasize the desirability of training officers by giving them a sequence of positions, and also simplifying the method of nominating candidates so as to obtain the best officer material.

Possible District boundary changes of one or two Districts are also under present consideration.

General Conclusions. The rate of membership growth is probably the best indication of active and effective Section operation. The recent change in the method of contacting graduating students should show a higher percentage of new members from that source. In general, the rate of growth in members for the next year is expected to be even higher than during 1949–50.

STANDARDS COMMITTEE

During the year, a number of steps in reorganizing Standards Committee activities have been accomplished.

The Standards Manual was revised and approved by the Board of Directors; the President of the Canadian National Committee of the International Electrotechnical Commission was made an ex-officio member of the Standards Committee; a liaison representative from Mexico was appointed to the Standards Committee; and a successful and satisfactory year has been enjoyed under the services of the new committee Secretary, J. J. Anderson, Jr., for whom the current year marks the first full year under his very capable surveillance.

In the field of Standards and Codes, the following were completed or revised during the year: AIEE *550*, "Master Test Code for Resistance Measurement"; *C37.1*, "Relays Associated With Electric Power Apparatus"; AIEE *43*, "Recommended Practice for Testing Insulation Resistance of Rotating Machinery"; *C57.15*, "Step Voltage and Induction Voltage Regulators"; a "Recommended Practice for Minimization of Interference From Radio-Frequency Heating Equipment"; AIEE *22*, "Air Switches, Insulator Units, and Bus Supports"; AIEE *57*, "Guiding Principles for Dielectric Tests"; AIEE *18*, "Capacitors"; AIEE *50*, "Automatic Circuit Reclosers for A-C Distribution Systems." The following were submitted to the Standards Committee and have been approved subject

to certain minor revisions which were referred back to their respective committees: AIEE *16*, "Electric Control Apparatus for Land Transportation Vehicles;" "Test Code for Aircraft Circuit Interrupting Devices."

Further action in connection with two other Standards has become necessary. For Standard *C55*, "Capacitors," for which AIEE is sponsor, a new ASA sectional committee is being organized to permit accomplishing adoption of this Standard as an American Standard. For Standard *C62.1*, "Valve and Expulsion-Type Lightning Arresters," Sectional Committee *C62*, for which AIEE is also sponsor, is being reactivated.

Another responsibility delegated to the Standards Committee by the Board of Directors this year is that of appointing representatives to the Electrical Section of the National Fire Protection Association. This step became a logical one since the AIEE interest in the Electrical Section of the NFPA is principally that occasioned by its responsibility for the National Electrical Code.

Co-operating with the ASA in a very appropriate effort to bring magnet wire into one sectional committee of ASA and all other wire—copper and aluminum alike—into one sectional committee, the Standards Committee withdrew AIEE sponsorship of the *C11* Sectional Committee on Hard Drawn Aluminum Conductors, in order that its scope might be combined with the Sectional Committee *H4* on Specifications for Copper Wire in a new sectional committee, *C7*, having for its scope: specifications for metallic conductors made of wire, whether for use in uninsulated form or for subsequent use in making insulated or covered cable.

The AIEE is, of course, represented on both the *C9* and *C7* sectional committees of ASA.

Recognition should be extended to the retirement of a number of AIEE representatives on various ASA sectional committees where noteworthy service had been rendered for many years in behalf of the Institute and the cause of voluntary standardization in the United States.

Special mention should be made noting the retirement of C. A. Powel, Past President of the Institute and Chairman of Standards Co-ordinating Committee Number 2, and of V. M. Montsinger, Chairman of Standards Co-ordinating Committee Number 3, past Chairman of the Standards Committee, and for many years past a most ardent worker in behalf of standardization both within the Institute and in ASA.

UNITED STATES NATIONAL COMMITTEE OF INTERNATIONAL ELECTROTECHNICAL COMMISSION

Dr. H. S. Osborne, Chief Engineer of the American Telephone and Telegraph Company, and heretofore, Senior Vice-President of the United States National Committee of the International Electrotechnical Commission, was elected President of the United States National Committee to succeed the late L. F. Adams. Dr. Osborne began his term of office in May 1949.

The year was an active one for the IEC, meetings of advisory committees being held as follows:

Advisory Committee 1—Nomenclature, Stresa, Italy, June.

Subcommittee 5A of Advisory Committee 5—Turbo-Alternator Sets, Brussels, September.

Advisory Committee 8—Standard Voltages and Currents, Stresa, June.

Advisory Committee 10—Insulating Oils, Stresa, June.

Advisory Committee 17—Switchgear, Stresa, June.

Advisory Committee 22—Electronic Devices, Stresa, June.

A.C. 28—Co-ordination of Insulation, Stresa, June.

A.C. 31—Flameproof Enclosures, Paris, November.

Subcommittee 34A of Advisory Committee 34—Lamps, London, July, and Paris, November.

Experts Preparatory Committee on Subcommittee 34B of Advisory Committee 34—Lamp Caps and Holders, Paris, November.

Advisory Committee 32—Fuses, Paris, May.

Committee of Action, Stresa, June.

Council, Stresa, June.

The group of meetings at Stresa was attended by 168 representatives of 14 countries, including a delegation of six from the United States, headed by Dr. Osborne.

At the meeting of the Council, Dr. Max Schiesser, Managing Director of the Brown-Boveri Company, was elected President of the International Electrotechnical Commission in place of E. M. Uytborck of Belgium, whose term had expired. Also at the Council meeting the revision of the Statutes and Rules of Procedure, which had been worked on for several years, was approved and declared in effect as of June 1949. These statutes and rules of procedure bring up to date fundamental documents of the IEC so that they should be a better guide to the orderly and systematic conduct of the work. At the meeting of the Council, attention was also given to the finances of the IEC by a Subcommittee on Finances which came to agreements which should place the finances on a sounder basis.

Technical progress was made in the committees which met during the year. A "Recommendation on Lamp Caps and Holders Together With Gauges for the Control of Interchangeability of Lamps" is approaching completion as an international recommendation.

During 1949, the United States National Committee initiated a review of all of the 35 technical projects of the IEC to determine whether or not those in the United States who are most directly concerned with the subject matter of each project are interested in continued participation of the United States in the work. In the past, the USNC has been represented on all these committees. In the review thus far, it has been decided that the USNC will continue participation in 20 projects, and discontinue participation in two projects. It is also concluded that the United States should relinquish one secretariat, though keeping membership on the committee. Thirteen projects remain to be studied to arrive at a decision on continued participation.

A group of 13 technical committee meetings and the Committee of Action will be held in Paris and London in July 1950. These meetings are as follows:

Advisory Committee 3—Graphical Symbols, Paris, July.

Advisory Committee 5—Steam Turbines, London, July.

Advisory Committee 12—Radio Communication, Paris, July.

Advisory Committee 17—Switchgear, Paris, July.

Advisory Committee 23—Electrical Accessories, Paris, July.

Advisory Committee 24—Electric and Magnetic Magnitudes, and Units, Paris, July.

Advisory Committee 25—Letter Symbols, Paris, July.

Advisory Committee 28—Co-ordination of Insulation, Paris, July.

Advisory Committee 32—Fuses, Paris, July.

Advisory Committee 33—Power Capacitors, Paris, July.

Advisory Committee 34A—Lamps, Paris, July.

Advisory Committee 35—Dry Cells and Batteries, Paris, July.

Committee of Action, Paris, July.

International Special Committee on Radio Interference (CISPR), July.

A strong delegation of American representatives will attend this group of meetings.

The work of the IEC continues to expand in scope and in interest to the electrical industry in the United States.

UNITED STATES NATIONAL COMMITTEE OF THE INTERNATIONAL COMMISSION OF ILLUMINATION

The ICI is an international organization of those interested in illumination. It is composed of national committees, representing most of the important countries of the world. Each nation may organize its own committee in any way that it sees fit, so long as it is truly representative of the country. The United States National Committee consists of some 40 persons from the following groups:

AIEE
Association of Edison Illuminating Companies
Illuminating Engineering Society
Optical Society of America
Society of Automotive Engineers
Society of Motion Picture Engineers
Members at large
Delegates to previous conventions

Most of the work of the ICI is carried on through some 25 committees to which the national committee appoints a representative. So far as possible, the work of these committees is handled by correspondence, and they report at the ICI meetings which are normally held once in three years. The next meeting will be in Stockholm in June 1951. At present, the secretariats for four of these committees are in the United States. They are: Colorimetry; Lighting of Public Ways; Lighting Practice (Interior); and Television Lighting. The United States National Committee also has a representative on each of the other 21 committees, and in addition the committee is also planning to offer four technical papers for the next conference.

At the general meeting held in Paris in 1948, the Central Bureau of the ICI previously located in England was moved to the United States. Carl A. Atherton, Member AIEE, is the Honorary Secretary. There is a fair possibility that the 1954 conference will be held in America. If this does take place, the work of arranging for it will fall largely on the United States National Committee. The attendance at Paris in 1948 consisted of approximately 200 delegates plus guests.

The work of the committees and of the Triennial Conference ICI are deemed to be very worth while, furnishing as they do an opportunity for experts from various countries to exchange data and views, and thereby promote the science and art of illumination. The International Commission on Illumination is the only international lighting organization.

COMMITTEE ON STUDENT BRANCHES

The Committee on Student Branches has studied and recommended to the Committee on Constitution and Bylaws changes in several sections of the Bylaws relating to Student

members, Student Branches and Joint Student Branches, Branch Counselors, the District Committees on Student Activities, and the Committee on Student Branches. The proposed changes are intended to clarify certain points regarding Student membership and to include the Chairmen of the District Committees on Student Activities as appointed members of the Committee on Student Branches, and also adjust the times for nominating and appointing Counselors and electing the Chairmen of the District Committees on Student Activities. The latter will enable the President-elect to appoint the members of the Committee on Student Branches at the same time other committee appointments are made. The proposal regarding the membership of the committee was approved in principle by the Board of Directors on June 23, 1949.

A subcommittee of the Committee on Student Branches has investigated the desirability of making an annual Branch award for outstanding student activity and has made the following recommendations:

1. That the AIEE make available a certificate of award to be given annually to one member of each Student Branch.

2. The certificate shall be awarded to the Branch member who has demonstrated the most outstanding Branch activities, particularly in the preparation or presentation of Branch, Section, or District papers, but with due consideration given to committee work, news publications of the Branch, co-operation with local Section, and so forth.

3. The recipient shall be selected by a committee of three consisting of the Counselor of the Branch and two Branch members appointed by the Chairman of the Branch.

4. The certificate shall be signed by national officers only—the President and the Secretary.

The committee recommended that the report be accepted as a progress report, and circulated to the full Committee on Student Branches for study and comments. Action will be taken on the subcommittee's recommendation at the June meeting of the committee.

With the authorization of the Board of Directors, the Chairman participated in two meetings of an "Inter-Society Conference on Engineering Student Chapters" on September 12, 1949, and January 27, 1950. These conferences were sponsored by the American Society of Civil Engineers, and were participated in by the following societies: American Road Builders' Association, American Institute of Chemical Engineers, AIEE, American Institute of Mining and Metallurgical Engineers, American Society of Civil Engineers, American Society for Engineering Education, American Society of Mechanical Engineers, National Society of Professional Engineers, and Society of Automotive Engineers. The purpose of these conferences was to obtain an exchange of ideas and views regarding the operation and objectives of Student Branches and Chapters. The first meeting was exploratory, and the second meeting took the action and made the recommendations that follow:

Action Taken

Recommendations of this conference upon release shall be referred to the respective societies for consideration by their committees on student activities or student chapters.

Recommendations of this conference shall be presented to the Engineers' Joint Council for the information of the Committee on Unity of the Engineering Profession, with the request that a new committee of EJC be set up for special consideration of problems of student organization.

Table IX. Section and Branch Statistics

	For Fiscal Year Ending April 30					
	1945	1946	1947	1948	1949	1950
Sections						
Number of Sections	73	75	75	81	84	87
Number of meetings held	884	1,210	1,333	1,340	1,561	1,605
Total attendance	96,346	113,531	155,649	109,637	128,025	135,847
Branches						
Number of Branches	125	125	126	127	129	130
Number of meetings held	547	716	1,018	1,172	1,350	1,298
Total attendance	17,132	22,844	40,669	77,040	103,828	80,672

Recommendations Agreed Upon

1. That student engineering organizations should be utilized to promote unity and professional consciousness among the students.

2. That at each college which does not have some organized co-ordination of engineering student groups there be formed a council or local society to advise and co-ordinate such groups.

3. That new engineering student activities be carried on by expansion and co-ordination within existing groups so far as practicable.

4. That there be prepared a set of general recommended principles regarding operation of engineering student societies for the guidance of college administrators.

5. That there be formulated a program of typical desirable activities for student engineering groups.

6. That student members of all approved student engineering groups be considered eligible upon graduation for membership in the national engineering organizations, without payment of an admission fee.

The report of the surveys of Student Branch membership as a function of maximum potential membership in each school has been transmitted to the Counselors of all Branches for their information and guidance. This report was prepared by the joint subcommittee of the Membership, Sections, and Student Branches Committees organized last year.

The committee held two meetings, one in Swampscott, Mass., on June 20, 1949, and the other in New York, N. Y., on January 30, 1950.

The Student Branches now number 130, of which 30 are Joint Branches with the Institute of Radio Engineers. The Student membership as of March 27, 1950, was 20,050.

TECHNICAL PROGRAM COMMITTEE

Technical activity in the AIEE, as evidenced by the presentation and publication of technical papers, has continued at a very high level, just under the record set by the previous year. This intense activity has occasioned some congestion, especially at the Winter General Meeting, where there were 58 technical sessions. There has also been a considerable increase in conference-type papers.

The Technical Program Committee has adopted a plan of operation through an Executive Committee composed of the Division Advisors and the appointed members of the Technical Program Committee. This Executive Committee is giving careful consideration to the trend toward conference papers and crowding at some general meetings. It is hoped that a better distribution of technical papers and sessions among the general meetings may be attained.

The effort to plan the program activities on an annual basis has succeeded very well through the co-operation of the technical committee chairmen and the Division Advisors. The preliminary estimates of sessions and papers have been surprisingly accurate, and are very helpful in guiding the Technical Program Committee.

Table X gives a summary of the programs for the year.

COMMITTEE ON TRANSFERS

Activities of the past two years have culminated this year in the preparation of an Operations Guide called "Transfers" and a Publicity Pamphlet entitled "Why Transfer?" both for use by Section Committees on Transfers. As of April 30, these pamphlets were in the final draft form ready for submission to the Board of Examiners and the Board of Directors for approval, following which they will be published.

The recommended Operations Guide officially presents a new conception of Section transfers work, including the development of uniform methods of procedure for guidance of the Section committees. The Publicity Pamphlet as recommended presents reasons why advancement to the higher grades should be of interest to members.

A report on results of the questionnaire sent to Section Committees on Transfers under date of March 18, 1949, consolidated with returns from the questionnaire dated March 22, 1948, was presented to the Committee on Transfers at its meeting in Swampscott, Mass., on June 22, 1949.

The main purpose of issuing the 1949 questionnaire was: to secure information for use in developing a manual of recommended

Table X. Number of Papers Presented During the Year Ending April 30, 1950

Meeting	District	Advance Copy Only	Conference Papers	Transactions	Total	Attendance
Summer, Swampscott	10	60	63	133	1,650
Pacific, San Francisco	10	36	17	63	878
Fall, Cincinnati	22	52	50	124	1,045
Winter, New York	14	137	92	243	3,218
North Eastern, Providence	18	2	14	34	502
Total	18	58	285	236	597	7,293

over-all transfers procedure; to reveal the present extent and nature of Section transfers activities throughout the Institute.

Replies to the 1949 questionnaire were received from 57 per cent of the Sections, representing 56 per cent of the total Institute membership. This volume compares with 33 per cent of returns in reply to the 1948 questionnaire; an increase of 73 per cent which it would seem is indicative of a substantially increased interest in transfers work throughout the Institute. A total of 53 Sections out of 84 (63 per cent) were heard from in reply to the 1948–49 questionnaires. Results submitted would therefore appear to be reliably representative of conditions throughout the Institute.

The questionnaire returns revealed the following information:

1. As of June 1949, 62 per cent of all Sections were engaged in transfers work.

2. Section committees used 16 different names for their respective committees. It has since been recommended, for purposes of uniformity, that all Section committees use the same name as the Institute committee, namely, "Committee on Transfers."

3. Of all Sections reporting, 43 per cent have standing Committees on Transfers, as compared with 57 per cent which do not. However, there does appear to be progress in amending Section Bylaws to provide for Committees on Transfers as standing committees, as initially recommended by the Committee on Transfers in its letter of December 30, 1946, to all Sections. It is hoped that all Sections will adopt this recommendation.

4. In the 48 Sections reporting, 216 members are in transfers work. The average number of Section members per committee men was found to be 72.

5. Regarding methods and policy used in handling transfers work, about 40 per cent of the Sections reporting appear to follow a procedure approaching that recommended in the 1946 letter to all Sections from the Institute Committee on Transfers characterized by complete coverage of Section membership; about 40 per cent engaged in moderate activities on transfers work by various methods; about 20 per cent engaged in little or no transfers activities.

6. About 75 per cent of all Sections apparently are afflicted with a condition of apathy relative to attaining higher grades of membership. How can AIEE grades be held in esteem by those outside the Institute if those within regard them so disinterestedly? Correction of this unhealthy condition is the aim of the method proposed in the Operations Guide.

7. When the Sections were asked for reasons for the foregoing conditions, the majority opinion was that the higher grades did not involve sufficient recognition benefit to induce members to seek advancement. The Publicity Pamphlet "Why Transfer?" and publicity in *Electrical Engineering* are expected to clear this point.

8. When asked how the apathy situation could best be corrected, the majority of replies confirmed the opinion of the Institute Committee on Transfers that the condition can best be overcome through encouragement of the Section committees by: provision of a manual of transfer procedure; and encouraging and assisting in publicizing the significance and advantages of the higher grades.

9. Many suggestions and criticisms were received concerning the over-all subject of transfers. These comments were reviewed and discussed at the June meeting in Swampscott, Mass.

The committee met a second time at the Winter General Meeting. Most of the time at this meeting was spent reviewing the first draft of the Operations Guide.

At the Winter General Meeting, the Chairman of the Committee on Transfers, by invitation, spoke at meetings of the Sections Committee on January 31, and the Membership Committee on February 1. The belief was expressed at these meetings that a milestone in AIEE progress is being reached through introduction of the Board of Review method of Section transfers work; that, when this system has been adopted by the majority of the Sections, rapid progress can be made toward the objective: "Each Member in the Highest Grade for Which He Is Qualified"; that when this objective is reached or closely approached the professional strength, prestige, and vitality of AIEE will have been greatly improved. It was pointed out that a situation such as presently exists with only 32 per cent of the membership in the directly professional grade (Member and Fellow) is not healthy. What this percentage would be if all members were in the highest grades for which qualified is not known, but it is believed that it would be in the neighborhood of 50 per cent.

Other projects completed by the Committee on Transfers during the subject fiscal year are as follows: outline of a publicity article for publication in *Electrical Engineering*; headquarters contacted relative to improvement of Year Book data and prompt notification of approved transfers; Committee on Constitution and Bylaws requested to amend Section 86 of the Bylaws to give the Committee on Transfers representation on District Executive Committees similar to the representation of the Membership Committee, as approved by the Committee on Transfers at its meeting on February 2, 1949; recommendations prepared for improvement of "Proposal" and "Application for Transfer" forms.

On April 7, 1950, a letter was sent to all Chairmen of Section Committees on Transfers outlining to them results of the 1949 questionnaire, informing them of the status of the proposed Operations Guide and Publicity Pamphlet, requesting a report on their transfer activities for the year ending May 13, 1950, and asking their opinion relative to the present requirement of five signers of the "Proposal for Fellow" form number 216 as compared with the former requirement of five Fellow or Member signers.

It is the considered opinion of the Committee on Transfers that the interest and activities of the Sections in this work was greater during the past year than in any other year.

Technical Committees

Co-ordinating Committees

COMMUNICATION, GENERAL APPLICATIONS, INDUSTRY, POWER, SCIENCE AND ELECTRONICS

It has been unnecessary to change the organization or scope of any technical committee. Some problems of overlapping jurisdiction have arisen, but these have been settled within the co-ordinating committees.

A difference of opinion exists on the matter of administrative jurisdiction of joint subcommittees. An opinion poll is under way, which will serve as the basis of action during the next administrative year.

The Communication Co-ordinating Committee, after functioning for one year, and based on the experience during that year, has recommended that the Committee on Aural Broadcasting Systems and the Committee on Television Broadcasting Systems be consolidated to form a new committee to be known as "Committee on Television and Aural Broadcasting Systems." The scope will be established before the end of the current administrative year.

With expansion of technical activities, it is desirable that the members of the Institute be kept informed of the programs of the various technical committees, their scopes, and general organization. This has been accomplished by continuation of the policy instituted last year of devoting a section in *Electrical Engineering* to news items concerning current activities of the technical committees. In addition, the 1949 Year Book for the first time includes a complete publication of organization and scopes for technical committees, subcommittees, joint subcommittees, and working, or project, committees. This information also will be included in future issues of the Year Book as a permanent policy.

In recognition of the fact that the title of the Committee on Servomechanisms does not properly define the scope of this committee, the Board of Directors approved the change in designation to "Committee on Feedback Control Systems."

The Board of Directors has approved the following changes, effective as of August 1, 1950:

1. Change in name of "Co-ordinating Committee" to "Division Advisory Committee."

2. Designation of the Chairman of the Division Advisory Committee as "Division Advisor."

3. Appointment of a new standing committee of ten members to be called "Technical Advisory Committee," which will replace the present Technical Activities Subcommittee of the Committee on Planning and Co-ordination.

4. Membership of the new Technical Advisory Committee to consist of the five Division Advisors, formerly called Co-ordinating Committee Chairmen, namely,

(a). Communication Division Advisor.
(b). General Applications Division Advisor.
(c). Industry Division Advisor.
(d). Power Division Advisor.
(e). Science and Electronics Division Advisor.

and

Chairman of the Technical Program Committee.
Chairman of the Standards Committee.

Three members-at-large to be appointed by the President, one of whom to be designated chairman of the committee.

5. The scope of the new Technical Advisory Committee is "to stimulate, promote, and encourage technical activities and specifically to be concerned with:

(a). All scopes of technical committees.
(b). Special events which may involve committees in more than one Division, such as special technical conferences, symposia, and general procedure.
(c). Joint subcommittees and other technical committee organization.
(d). Assistance to the Technical Program Committee, the Standards Committee, and the Committee on Planning and Co-ordination, when solicited.
(e). Consideration of problems brought up by any Technical Division."

6. The Chairman of the Technical Advisory Committee to be a member of the Committee on Planning and Co-ordination.

7. The several Division Advisors no longer to be members of the Committee on Planning and Co-ordination, or Committee on Award of Institute Prizes.

After the approval of the foregoing items, the Board of Directors voted to eliminate from the Bylaws provisions for ex officio memberships of committees.

The foregoing changes give recognition to the previously stated policy that the grouping of technical committees into Divisions, formerly Co-ordinating Committees, does not deprive the chairman of a technical committee of any prerogatives which he had prior to such grouping; the success of the Institute technical activities will continue to depend upon the degree of voluntary co-operation by each technical committee chairman; the Division Advisor will represent the committees within his Division; the creation

of a Technical Advisory Committee will provide the long-needed medium for the exchange of views among Division Representatives and the formulation of recommendations relating to technical committee activities.

During the year, a manual of instructions for technical committee chairmen was completed, and it will be distributed to incoming chairmen. It is intended as a source of information to new chairmen for their general guidance in the performance of their duties.

Technical conferences on specialized subjects continued in popularity during the year, as evidenced by the large attendance at each conference. The success of these conferences is due in part to the willingness of local Sections to act as sponsoring hosts and to arrange for the necessary meeting facilities and publicity. Some technical committees are now sponsoring annual and semiannual conferences under a continuing program. Conferences are scheduled also with societies outside of the Institute—Instrument Society of America, Institute of Radio Engineers, National Telemetering Forum, Radio Manufacturers Association, and so forth. Reports on the conferences held during the past year are given under the heading "Special Technical Conferences."

Technical activities in general continued at a strong pace during the year, taxing the facilities available for parallel sessions during the general meetings. The problem of accommodating the number of papers requiring preprinting and publication in *Transactions* was not too great, due to the combining of the 1950 Summer and Pacific General Meetings, and the co-operation of committee chairmen in estimating their requirements at least one year in advance. Although these matters are primarily the responsibility of the Technical Program Committee, successful operation must depend upon the co-operation of the individual technical committee chairmen, which has been accomplished through the assistance of the Division Advisors.

Communication Group

COMMITTEE ON AURAL BROADCASTING SYSTEMS

The activities of this committee were devoted to the procurement and review of technical papers, and minor participation in review of several Standards referred to it by the Standards Committee. The committee covers a field that is relatively stabilized and at present inactive because of the shift of interest to television. Therefore, on August 1, this committee and the Committee on Television Broadcasting Systems will be combined, and the new committee will be known as "Committee on Television and Aural Broadcasting Systems." During the year, the committee furnished, upon request, some material on the outstanding developments in the field of aural broadcasting for inclusion in an article for *Electrical Engineering*.

COMMITTEE ON COMMUNICATION SWITCHING SYSTEMS

The committee held one well-attended meeting in New York on September 15, 1949, for the purpose of discussing committee work plans for the year. At this meeting, specific papers to be sponsored for the Winter General Meeting were discussed and plans for this meeting were crystallized. Also, tentative plans for the next two general meetings were discussed.

The committee sponsored three formal papers at the Winter General Meeting. The session was well-attended, and each of these papers was followed by stimulating discussion.

The committee is sponsoring three papers at the Summer and Pacific General Meeting. The papers chosen are on closely related subjects, and are particularly appropriate for this meeting, since they are concerned with telephone switching equipment now in service on the Pacific Coast in both Bell and independent operating companies.

Special consideration has been given to plans for the Fall General Meeting, in view of the expressed need to build up interest in this meeting. The committee considered that, while this location is not best suited for papers on the large city switching systems, it would be quite an appropriate location for a symposium of papers on the small community dial office systems. Also, the committee thought it very desirable to obtain participation by both Bell System and independent fields in the meeting.

COMMITTEE ON RADIO COMMUNICATION SYSTEMS

This committee held one formal meeting, on February 1, 1950. Most of the committee activities were conducted by mail and by telephone. The chairman of the committee attended several meetings of the Technical Program Committee.

The committee reviewed a number of technical papers, most of which have been presented at AIEE meetings and some recommended for publication. This effort is being continued to arrange for papers for presentation at future meetings. The committee is co-operating with the Committee on Carrier Current in arranging for the presentation of papers concerning the use of microwave radio equipment for relaying, telemetering, and supervisory control for electric power distribution systems.

The committee sponsored one session with three papers at the Fall General Meeting, and two sessions with six papers at the Winter General Meeting.

The Mobile Radio Subcommittee has undertaken the study of the protection of base stations in mobile radio service against damage by lightning, in co-operation with certain members of the Lightning and Insulator Subcommittee.

COMMITTEE ON SPECIAL COMMUNICATION APPLICATIONS

During the past year, the committee held one full committee meeting and sponsored one technical session. This committee's work is largely devoted to subjects which do not logically fall within the scope of the other communication committees.

A full technical session was sponsored at the Fall General Meeting, on railroad communication, which proved to be of considerable interest. Much of the work in arranging this session had been done by the committee when it was a subcommittee of the Committee on Communication.

In expanding to full committee status, some members were added to the original subcommittee, and it is expected some growth will occur in the first few terms of the committee. At the meeting held during the Winter General Meeting, much time was devoted to searching for areas that are not covered by the other committees. Three subcommittees have been organized, and they are endeavoring to find sources of technical papers on subjects of train control, centralized traffic control, caboose power supplies, communication, and train entertainment. In the field of electroacoustics, material on public address systems and recording schemes are highlighted as the most logical for investigation. The Subcommittee on Special Activities expects to get into the subjects of ceramics, ferrites, and materials with high dielectric constants.

COMMITTEE ON TELEGRAPH SYSTEMS

One meeting of the entire committee was held during the year, at the Winter General Meeting. The committee reviewed its program in furtherance of which it had presented a paper on an electronic regenerative repeater and one on a submarine cable carrier at the Winter General Meeting. There was consensus of opinion that the application of electronic distributors to multiplex telegraph and radiotelegraph circuits is of interest to the profession, and that a symposium of papers should be developed for the Fall General Meeting. Subsequent developments have thrown doubt upon the advisability of presenting such a symposium where the prospective audience would be too small to support the papers with adequate discussion, there being a considerable concentration of telegraph engineers in New York and Chicago.

There was also consensus of opinion that a comprehensive paper on American and possibly foreign telegraph printers should be developed. Substitution of aluminum for copper in certain line applications also will be watched for developments. In the submarine cable field, it is expected that submerged repeaters will soon command attention.

The Subcommittee on Facsimile reported on the conference session on its subject held at the Winter General Meeting. The conference itself proved to be an attraction to every segment of the facsimile industry. Particularly stimulating was an address by the officer heading the Armed Forces' development and procurement activities, who emphasized the essential nature of facsimile to military operations and the unity of effort now being applied to the solution of outstanding problems.

COMMITTEE ON TELEVISION BROADCASTING SYSTEMS

This committee was newly formed this year, and devoted all of its activity to initiation of technical programs, solicitation and review of timely papers, and the conduct of sponsored sessions. The field of activity is divided between transmission systems and receiving systems, each being covered by a separate subcommittee. During the year, the committee sponsored two complete technical sessions, at which eight papers of interest to the membership in the field of television were presented. One of these sessions was at the Fall General Meeting; the other at the Winter General Meeting.

While no specific standardizing activities were undertaken during this first year of the committee, a number of proposals before the Standards Committee were reviewed and comments submitted, where necessary. A

brief statement on television developments in 1949 was prepared for publication in *Electrical Engineering*. Particular effort is being directed toward obtaining papers on the more general aspects of television systems which are of interest to the over-all membership, and effort is being directed toward arranging for additional sessions at future meetings.

COMMITTEE ON WIRE COMMUNICATION SYSTEMS

This committee was formed as a full committee at the time the Communication Group was split from the Communication and Science Group. Meetings were held in September 1949 and in February 1950. One serious problem faced by this committee is that the members are so widely spaced geographically it is very rare for some of them to be able to attend meetings held in the East. Such wide geographical spacing is desirable, of course, to cover the field as thoroughly as possible. To alleviate this situation, it is proposed to hold committee meetings at all general meetings so that each member will be able to attend at least some meetings. This procedure should stimulate interest, make new members available, and, perhaps, increase the number of papers from the western part of the country.

A complete session was sponsored at the Fall General Meeting. A joint session at the Winter General Meeting was sponsored with the Committee on Telegraph Systems. A joint session at the Summer and Pacific General Meeting is planned, and a complete session is planned for the Fall General Meeting. Some papers are already scheduled for the Winter General Meeting and for the 1951 Summer General Meeting.

General Applications Group

COMMITTEE ON AIR TRANSPORTATION

The committee held one meeting of the entire committee, in San Francisco, on August 22, preceding the Pacific General Meeting. Approval was voiced of the plan to concentrate technical sessions at one principal meeting during the year, alternating between the eastern and western sections of the country. It was further decided that areas in which aircraft activities are located should be chosen for the meetings. In view of this, the committee decided to concentrate on technical papers to be presented at the Middle Eastern District Meeting, Baltimore, October 3–5, 1950. A meeting of the committee has been scheduled for October 2, in Baltimore.

Aircraft Electric Rotating Machinery Subcommittee. The subcommittee activities have been concentrated on rewriting Test Code No. 800 for reissue. A subcommittee meeting was held in New York on February 2 to review the material on hand. Most of the work has been completed, and it is expected that a draft of the code will be circulated to the committee for review and approval. It is further expected that the revised Test Code No. 800 will be submitted to the Institute during the summer.

Aircraft Electric Control, Protective Devices, and Cable Subcommittee. The "Test Code for Aircraft Interrupting Devices" that was submitted to the Standards Committee in July 1949 was acted on by letter-ballot. As a result of the ballot several criticisms were received that the Standards Committee believed should be considered before publication of the test code. These criticisms were referred to the subcommittee.

A similar Code for Carbon Pile Regulators is in the process of being prepared for submission to the Standards Committee.

Basic Principles of Altitude Rating Subcommittee. This subcommittee has experienced considerable difficulty in obtaining and compiling data on which to base a Standard on the Basic Principles of Altitude Rating of Electric Machinery. It is continuing its efforts to complete present data, and will extend them from 50,000 feet to 60,000 feet and further if practicable.

Aircraft Electric Systems Subcommittee. This committee is engaged in preparing new material for inclusion in the "Report on Aircraft Electric System Guide," AIEE *750*, issued in July 1947. This will be a continual process as data become available for new sections or revision of existing sections.

COMMITTEE ON DOMESTIC AND COMMERCIAL APPLICATIONS

The subject of domestic and commercial applications is one in which general interest by AIEE members is only awakening. It exists, but has been dormant. In the preparation of meetings and technical conferences, it has often been necessary to solicit papers from outside the Institute membership. The time has not arrived where the committee receives many voluntarily submitted papers. Hence, the time factor in arranging a session is vital, and it is difficult to get papers prepared long enough in advance for the usual review. Time and continued committee activity and enthusiasm will help correct this situation. Meanwhile, the need of continuity is evident, as papers may have to be started during one administrative year for presentation during another.

The subject of electric heating of houses, whether by full conversion of electric power input by resistance heating, or by partial conversion of electric power input to extract heat from earth, air, or water by a pump, is of widespread interest not only to home owners, but also to public utilities, and the committee thinks it important to keep the Institute informed on developments in the field by appropriate meetings in the future.

The manufacture of domestic appliances is a substantial segment of American industry. The energy to operate electric appliances in the home makes up a substantial part of the load on power systems. A great deal of high-class engineering is involved in this field. An unusual opportunity exists for service to the people of the nation. It is worth while for the Institute to recognize the magnitude and opportunity of engineering in this area, and to take steps to attract into its membership those who are already active in its engineering phases.

The committee held a meeting in New York, on February 3, at which ten members were in attendance. Notices of the activities of the committee have appeared from time to time in *Electrical Engineering*, in the section devoted to "Committee Activities."

L. R. Emmert has been appointed the committee's delegate to the National Farm Electrification Conference, with L. N. Roberson as alternate.

The committee has organized three subcommittees to carry out its objectives.

Subcommittee on Electric Heating of Houses, and Heat Pumps, for the West Coast. This subcommittee organized and held a special technical conference in its field in Medford, Oreg., on April 12.

Subcommittee on Electric Heating of Houses, and Heat Pumps, for the East. This subcommittee sponsored a session at the Winter General Meeting. Five papers were presented, three on heat pumps, and two on electric resistance heating, and 155 persons attended the session.

Subcommittee on Domestic Appliances. This subcommittee has arranged a special technical conference to be held in Cleveland, Ohio, on June 20, in co-operation with the Cleveland Section.

COMMITTEE ON LAND TRANSPORTATION

This committee has continued to keep in active touch with the developments in the field of electric transportation. The outstanding developments during the past year have been the development of the gas-turbine electric locomotive, and the application of ignitrons to railroad motive power to enable the advantages of high-voltage a-c power transmission to be combined with the advantages of the d-c traction motor for train propulsion. Papers on both of these developments were presented at the Winter General Meeting, and these subjects will be actively followed by further papers and reports. The continuing development and application of diesel-electric motive power has been reported in the form of various papers covering the details of improvement to this type of motive power for the Winter General Meeting, and the 1950 Summer and Pacific General Meeting.

The developments in urban transportation equipment are being followed, and papers are being prepared for presentation at future meetings of the Institute in connection with this particular application. Subcommittee activity continues in connection with the review of AIEE Standards applicable to this committee assignment, and to the continuing collection of data relative to the existing railroad electrification development, both in this country and abroad.

One committee meeting was held in connection with the Winter General Meeting, at which 17 members of the committee were present, and further meetings are planned for during the year as opportunity permits.

COMMITTEE ON PRODUCTION AND APPLICATION OF LIGHT

A very lively conference session on long tube fluorescent lighting was held as a part of the Winter General Meeting. As has been the custom, a meeting of this committee was held at that time. Attendance was unusually good, due to consideration that was being given to a recommendation to Standards Committee on approval of Illuminating Engineering Society "Recommended Practice for Office Lighting" as a possible American Standard.

Discussion of committee activities during the year led to a decision to hold one lighting session each year, with preference being given to the Winter General Meeting. A list of possible subjects for next year's session

was suggested. A plea was made for papers on related subjects which might be published in *Electrical Engineering*. Subcommittees were inactive during the year.

COMMITTEE ON MARINE TRANSPORTATION

The committee held one well-attended meeting at Institute headquarters on April 14, 1949. The committee has been working on revisions to "Recommended Practices for Electrical Installation on Shipboard," as issued in December 1948. The committee also has been working on the international standardization of electric installations on shipboard.

Subcommittee Activities. The subcommittees have been quite active, each reviewing the sections of Standard *45* under its cognizance, and making reports to the main committee.

Industry Group

COMMITTEE ON CHEMICAL, ELECTROCHEMICAL, AND ELECTROTHERMAL APPLICATIONS

The committee held one session at the Summer General Meeting, and two sessions during the Winter General Meeting.

During the past year, the work has followed the pattern set during the preceding year. In the past year, the Metallic Rectifier Subcommittee was elevated to full committee status in the Institute and removed from the jurisdiction of this committee.

The activity of the subcommittees is outlined in the following:

1. *Arc Furnaces and Electrothermal Processes.* This subcommittee continues to study the problems of arc furnace application. The problems of surging and regulation are again coming to the fore, and are being actively studied. A session is planned for the 1950–51 season.

2. *Electrolytic Processes.* This subcommittee is continuing its work on subcommittee report on influence of cell line characteristics on the selection of electric power and conversion equipment.

3. *Cathodic Protection.* This subcommittee has been inactive during 1949–50, due to the resignation of the chairman and inability to obtain a new chairman. A new chairman has now been appointed, and full activity is expected next year. The committee is planning a session on corrosion.

4. *Petroleum Refining and Production.* This subcommittee has been relatively inactive during the current year. However, activity is planned for the 1950–51 season.

5. *Batteries, Battery Forming and Charging.* This subcommittee has been very active this year. An excellent conference session was sponsored at the Summer General Meeting, and additional meetings are planned for 1950–51. The committee is continuing its work on the inconsistencies in the Storage Battery Standards and is making every effort to have these problems resolved in the near future.

6. *Chemical Industries.* This subcommittee sponsored two sessions at the Winter General Meeting, on the application of power cables in chemical plants. There continues to be great interest in this subject, and further sessions are planned for the next Winter General Meeting to attack the installation problem. The subcommittee is continuing its study of the application of equipment to this industry.

COMMITTEE ON ELECTRIC HEATING

The committee has generally agreed that it will emphasize the Winter General Meeting as a time for general paper presentation, with an investigation going on as to the prospects for a Conference on Electric Heating in the midwest area, similar to the biannual Welding Conference. This plan was decided on at the committee meeting in New York on January 30, 1950. Meanwhile, the work of the subcommittees is going on as follows.

Subcommittee on Induction and Dielectric Heating is co-operating actively with the Federal Communications Commission on reports of radio interference from heating equipment. Members are working on assigned sections of proposed equipment Standards and performance tests. Some sections have been received and are being edited and reviewed. Work on definitions is being co-ordinated with the Institute of Radio Engineers.

Subcommittee on Radiation Measurements Above 200 Megacycles is working actively on preliminary Standards in this field. With several FCC personnel included in its membership, co-operation and field tests are progressing satisfactorily. Various sections are to be submitted at the next meeting for editing and review.

Radiant Heating Subcommittee has been working with the Ovens and Furnaces Committee of the National Fire Protection Association to extend and clarify Standards for electric equipment for Class *A* ovens and furnaces. These proposed Standards presumably will become effective on June 1, 1950. Meetings are continuing to sponsor investigation of controversial questions regarding various sources of infrared radiation.

Subcommittee on Resistance Heating and Electric Furnaces is planning to recommend that its title and scope be limited to resistance heating. A working group is being organized to collect, edit, and disseminate information on various resistance heating applications, probably in a loose-leaf handbook form.

COMMITTEE ON ELECTRIC WELDING

The activities of this committee have been directed toward fostering interest in electric welding, organizing subcommittees for study and research on this subject, and sponsoring a "Special Technical Conference on Electric Welding." A special technical conference was conducted in co-operation with the American Welding Society and the Industrial Electrical Engineers Society in Detroit. The purpose was to bring industrial electrical engineers together in a conference on subjects in which all were primarily interested. The committee plans to hold a similar Electric Welding Conference every other year.

The committee conducted a session during the Winter General Meeting, and held a number of committee meetings during the year for planning its activities, including the work necessary for the conference.

Subcommittee on Power Supply for Resistance Welding is continuing its work on a special report, and, during the February 2 meeting of the main committee, two working groups were recommended for addition to the Power Supply Subcommittee, namely, Working Group on Probability and Working Group on Proposed Protection Devices in Welding. However, during a meeting of the subcommittee, it was decided that this work, because of its nature, should be included with that of the Users Working Group instead of in a separate group. The subcommittee, in order to cover all interests in power supply for welders, has a Users Working Group, a Manufacturers Working Group, and a Utilities Working Group, with each preparing a section of the special report. The special report of this Power Supply Subcommittee should be available in the near future.

Subcommittee on Welding Research was organized during the year. This subcommittee hopes to increase the efficiency and usefulness of the electric arc research by: the interchange of information on past, present, and planned future research activities; the co-ordination of active research projects through mutual co-operation; the definition of basic electric-arc problems which need further study and research; the stimulation of technical papers and sessions on electric arcs; encouraging the education of graduate students for electric-arc research; and bringing the needs and advantages of electric-arc research to the attention of industrial and other potential sponsors for research. It plans to initiate this program by: preparing a reasonably complete bibliography of past research in the field of high-pressure electric arcs; preparing a summary of nonconfidential electric-arc research projects in effect at present; and defining the basic electric arc problems which must be studied now. Should the subcommittee be successful in carrying out the three initial phases outlined, the material it has collected and organized may serve as a basis for significant technical papers and for sessions or conferences on high-pressure electric arcs. Publication of such information and indication of useful research projects for the future might lead to increased interest on the part of industry and other potential sponsors of fundamental research.

COMMITTEE ON FEEDBACK CONTROL SYSTEMS

Last fall, the committee was formed to take over the duties previously delegated to the Joint Subcommittee on Servomechanisms. While this action necessitated no drastic change in the objectives of the group, the change to full-committee status appreciably enhanced the opportunities for effective operation. The committee had 32 members at the close of the year.

The scope of the committee covers the treatment of matters in which the dominant factors are the terminology, requirements, design, construction, and operation of equipment, and the circuits pertaining to control systems involving feedback, such as servomechanisms, regulators, and governors, excluding measuring and recording instruments. This committee co-operates by means of liaison membership with other technical committees within the Institute interested in servomechanisms, regulators, or other control systems, as well as with related committee work in associated societies.

Participation in two Institute general meetings during the year consisted of the sponsorship of ten papers, of which one was a subcommittee report on terminology. The two prize-paper awards in the Industry Group announced at the Winter General Meeting were for papers sponsored by this committee. At the Summer General Meeting, a joint session was held with the Committee on Industrial Control, and at the Winter General Meeting a joint session with that committee and a session on feedback control were held.

Subcommittee on Terminology and Definitions. Because of the rapid growth of professional activity in the field of feedback control, the problems regarding unified terminology and definitions pertaining to such devices as servomechanisms, regulators, and amplifiers are many. This subcommittee was appointed to work on the subject in co-operation with subcommittees of other Institute technical committees. During the year, three subcommittee meetings were held. At the Winter General Meeting, a conference paper report on the work of this subcommittee in collaboration with similar committees in ASME, ASA, and AIEE was given. Future activity is expected to define basic terms, and prepare a glossary of symbols, terminology, and specifications for performance.

Related Activity. One of the important functions performed by the committee has been to advise the editorial staff of *Electrical Engineering* on the suitability of manuscripts. Formal AIEE activity in the field of feedback control systems has stimulated many manuscripts in this field. Codifying these manuscripts and recommending their allocation either to *Electrical Engineering* or the Technical Program Committee has been a large activity. At the close of this year, a backlog of manuscripts was under review for the *Transactions*.

Future Activity. Consideration has been given to the feasibility of scheduling an AIEE conference on feedback control systems late in 1951.

Because of the wide geographical distribution of the interest in feedback control systems, this committee has appointed subcommittee groups on the West Coast and in the Middle West.

COMMITTEE ON GENERAL INDUSTRY APPLICATIONS

The activities of this committee have been directed toward fostering interest and coordinating activities within the various subcommittees, and sponsoring "special technical conferences," where industrial electrical engineers can meet others in the same or allied fields and discuss electrical applications. Industrial processes in a mass production age offer numerous and diversified opportunities for the application of equipment utilizing electric power. The use of electric power in industry has increased 118 per cent (from 79.0 to 171.5 billion kilowatt-hours) in the last ten years (1939 to 1949) and accounts for 57 per cent of all the power used in the United States. Programs of the special technical conference type are ideally suited for discussing problems associated with an industry or a group of related industries.

The committee held two general meetings during the year, one in Cincinnati, in October 1949, and the second in New York, in February 1950. At both of these meetings, plans for future activities were discussed. The committee sponsored a technical session at the Winter General Meeting, on the subject of "Explosion Hazards in Industry and Their Relation to Electrical Installations." A second session on this general theme is being planned for the 1951 Winter General Meeting. A technical session is also being planned for the Fall General Meeting.

The activities of subcommittees covering specific assignments are summarized in the following.

Subcommittee on Machine Tools. This subcommittee organized three sessions on machine tools for the Fall General Meeting. Ten papers discussing machine tool applications and problems were presented at the three sessions, which were well attended. This subcommittee is planning on holding a special technical conference in New England next fall.

Subcommittee on Rubber and Plastics Industry. This group has arranged to hold, jointly with the Akron Section, an annual special technical conference in Akron. The program this year was an all-day session on May 5.

Subcommittee on Textile Industry. A conference was held in Atlanta on April 13 and 14, and a session was held at the North Eastern District Meeting.

Subcommittee on Pulp and Paper Industry. In connection with the West Coast Subcommittee, this group is planning a technical session at the Summer and Pacific General Meeting, the theme being "Lumber and Paper Mills." It will feature papers on the application of electric equipment to saw mills, paper machine drives, and pulp mills.

Subcommittee on Materials Handling. A technical session on factory elevators and hoists is being planned for presentation at the 1951 Winter General Meeting. Freight elevators form a vital part of the material-handling system in multifloor factories, warehouses, garages, and other types of buildings. Each freight elevator installation usually involves a special engineering study, and the session will be of interest to engineers who have the problem of determining elevator requirements and types of equipment for industrial plants.

The subcommittee work discussed does not cover, by any means, all the industries which come within the scope of the committee. One of the problems discussed at the February 2 meeting was the organization of additional subcommittees to cover other industries, such as food processing, and the ceramic and cement industries, where the electrical engineering problems of general interest to these industries may be discussed.

This committee thinks there is no better way to further engineering knowledge and bring the AIEE close to engineers working on industrial problems than to bring together in technical sessions and conferences a group of these engineers. The committee has met with some degree of success in this task. Effort will be made to make the work more effective in the future through a long-term planning program.

COMMITTEE ON INDUSTRIAL CONTROL

The committee held two meetings, and sponsored five technical sessions, three of which were held in conjunction with other committees of the Industry Group. The following projects have been worked on by the various subcommittees.

Subcommittee on Standards has completed work on a proposal to revise the Industrial Control Section of ASA Standard *C42*, "Definition of Electrical Terms," which is sponsored by AIEE. The proposal is now in the hands of ASA Sectional Committee *C42*, to be considered for the final revision of that Standard. Another AIEE sponsored Standard is ASA *Z32.12*, dealing with graphical symbols for electric apparatus. This Standard has been in use for several years, and its acceptance by industry has been very satisfactory in general. However, certain criticisms have been raised in some industries claiming inadequacy of certain symbols. For this reason, the committee has started a study of the basic symbols with the aim of resolving difficulties.

Subcommittee on Electronic Control, through its working groups, has been active in discussing definitions of terms. This work is approaching completion, and it is expected that, during the ensuing year, proposals for definitions will be presented to the proper ASA channels.

Subcommittee on Bibliography has completed the draft of a comprehensive bibliography on industrial control, which includes brief abstracts on all important American and foreign literature on the subject. The final draft of the manuscript is being prepared for printing as an AIEE publication.

Subcommittee on Regulators and Feedback Control Systems has been newly formed. The subcommittee will provide liaison with other committees operating in related fields, and special emphasis is laid on the importance of such systems for industrial applications. The first project of the subcommittee is the development of system classifications and definitions.

COMMITTEE ON INDUSTRIAL POWER SYSTEMS

The committee has been quite active this year, starting with two sessions at the Fall General Meeting, one of which was sponsored jointly with the Committee on Industrial Control. Three committee meetings were held.

On April 19–20, a Power Conference was held in Pittsburgh under the joint sponsorship of the Pittsburgh Section, the Committee on Power Generation, the Committee on Industrial Power Systems, and the Committee on System Engineering. This first Power Conference was very well received, and the sponsoring committees have been strongly urged to present another in the near future.

For the Summer and Pacific General Meeting, the committee is sponsoring a session, jointly with the Committee on Chemical, Electrochemical, and Electrothermal Applications, on problems in the petroleum field.

Subcommittee on Revision of "Electric Power Distribution for Industrial Plants." This subcommittee has been working actively to prepare a revised and improved edition

of the report. This work has not reached the publication state as early as anticipated, but should be ready early next year.

Subcommittee on Wiring Design for Commercial Buildings. This subcommittee prepared its report in published form in time for announcement at the Fall General Meeting. The report contains a wealth of information, including quick-estimating charts and valuable check lists, which will be helpful to anyone interested in the wiring design for large commercial buildings.

COMMITTEE ON MINING AND METAL INDUSTRY

This committee is continuing its program of presenting papers of interest to the electrical engineers in the fields of mining and metal. There are two active subcommittees. The Mining Subcommittee includes members interested in bituminous coal, anthracite coal, potash, copper, and other ores. The Metal Subcommittee includes members in the fields of steel, copper, aluminum, and other nonferrous metals. The committee sponsored two sessions on mining and one session on metal at the Fall General Meeting, and has arranged for two sessions on mining and one session on metal at the Summer and Pacific General Meeting.

The present program of the committee includes the development of Standards, co-operation with the American Mining Congress and the Association of Iron and Steel Engineers, and the sponsoring of sessions which will interest primarily the electrical engineers working for the mining and metal industries. In addition to having many members on the committee who are also members of the Association of Iron and Steel Engineers and the American Mining Congress, the committee has one member each assigned as liaison between it and these organizations. The committee hopes to develop technical conferences which can be scheduled in such locations and at such times that the co-operation of the other two organizations can be obtained.

One item of special interest is that a representative of *Coal Age*, a publication for the mining industry, covered the mining sessions at the Fall General Meeting, and gave a good write-up with favorable publicity for AIEE in an issue immediately following the meeting. Arrangements have been made to have the *Engineering and Mining Journal*, a publication for the hard rock mining industry, cover the two mining sessions at Pasadena in the same manner.

Power Group

COMMITTEE ON CARRIER CURRENT

During the year, the committee held four meetings, and sponsored one conference-type session on microwave applications at the Summer General Meeting. Much of the work is carried on by subcommittees.

Subcommittee for Preparation of a General Interest Paper on Carrier Current is approaching the end of its work, and it is expected to go out of existence.

Subcommittee to Report on Application Guidances for Carrier Current is also completing its assignment, which has been carried on essentially by one man, and will cease to exist.

Subcommittee on Methods of Measurement is checking its report against field observations, and modifying the report from time to time in minor details to promote simpler or more accurate methods of field testing.

Subcommittee on High-Frequency Characteristics of Power Equipment originally planned to carry out factory tests. However, it develops that in most plants this would cause undue interference with the routine of production. It thus appears that such data will be derived from tests of equipment in the field.

Subcommittee on Carrier Current Characteristics of Transmission Lines and Systems has obtained excellent response to some 130 copies of a questionnaire, but unfortunately very little of the information is in such form as to be useful for comparison with other field observations. Up to the present time, field tests were conducted on a random basis, in general, observing only relative values.

Subcommittee on Standard Terminology for Carrier Current has completed its report, and will go out of existence as soon as co-ordination with the Standards Committee is completed.

Subcommittee on Long Life Tubes is assembling information from both manufacturer and user sources, and will draw up a report with recommendations.

Subcommittee on Use of Microwave Equipment for Relaying, Telemetering, and Supervisory Control has been most active. It provided material for a conference session at the Summer General Meeting, and is presently assembling papers for a full technical session at the Summer and Pacific General Meeting.

Subcommittee on Operating Experience With Carrier Current Relaying Channels has sent questionnaires to at least the major users o carrier equipment, and is assembling and tabulating the replies.

Plans for the coming year include a technical session on microwaves and a conference session on carrier current during the Summer and Pacific General Meeting. At the same time, it is planned to call a meeting of the entire committee, and invite all interested parties to attend. The subcommittee seeks an expansion in membership, especially on the West Coast, and plans to establish a West Coast Division, possibly under a second vice-chairman. The general objectives remain about the same, but will be adjusted, as required, to cope with new factors as they arise.

One new element is Federal Communication Commission Docket Number 9288 in which it is proposed to expand the low power rule so that power-line carrier would be specifically included. Many interested organizations are co-operating with the FCC in making field observations. The committee is interested in the academic factors, and will assemble field data from all possible sources to expand knowledge of propagation from practical lines in clear areas, as well as those in which the field will be distorted by foreign objects.

COMMITTEE ON INSULATED CONDUCTORS

Organization. The committee has 48 members and, in addition, 46 special members who serve only on subcommittees. The initial organization of this new committee into 12 subcommittees has continued. This arrangement has facilitated carrying out one of the main reasons for forming this committee, that is, to form avenues for considering all types of projects relating to research, design, installation, and operation of various types of insulated wires and cables.

Committee Meetings. The committee is pursuing the policy of having two meetings during each administrative year. The first is for one day, and is held in the fall in the East (has been New York). The second is for two days, in order to allow ample time for subcommittee meetings and for general informal discussions, and this meeting is held in the Middle West (to be held in Chicago in May this year). The average attendance at the committee meetings has been about 60. In addition, the Administration Subcommittee has had two meetings at the time of AIEE general meetings.

Projects. The subcommittees have over 90 projects under consideration. In addition, informal reports on various items of general interest are being presented at the meetings. The discussions of these projects and of the reports, and the records thereof in the minutes, are helping make the activities of considerable value to the members and special members.

Standards. Recently, the work on revising the definitions for wires and cables was completed and forwarded to the ASA Sectional Committee *C-42* for its use in the revision of "Definitions of Electrical Terms." Work on other Standards and test codes is under way by the committee.

Technical Papers. Twelve papers obtained by the committee were presented at three technical meetings of the AIEE. It is to be noted that a good share of these pertain to subjects such as design of cable accessories, which were not given the attention that they might have had under the AIEE committee organization that obtained several years ago. In addition, a summary of information and conclusions drawn from a survey conducted by the committee on practices relating to protective coverings for lead-sheathed power cables was published in *Electrical Engineering*.

COMMITTEE ON POWER GENERATION

The committee held three meetings during the year, the first at the Summer General Meeting, the second at the Fall General Meeting, and the third at the Winter General Meeting. The activities of the committee, as reported by the various subcommittees, are as follows.

Prime Mover. Preliminary talks with The American Society of Mechanical Engineers representatives have indicated their willingness to discuss the feasibility of setting up Standards for turbines rated at 7,500 kw and smaller.

Station Design. Through the efforts of this subcommittee, a session was organized on "centralized control," at which papers and discussions were presented in favor of and against centralized control. The subcommittee is sponsoring two sessions for the 1951 Winter General Meeting, one on the co-ordination of station design and analysis of plant operating troubles, and another on safety and fire-fighting equipment.

Speed Governing. A session was held at the Fall General Meeting. Specifications for governing of steam turbines 500 kw and up were completed by the joint AIEE-ASME Committee on Speed Governing Specifica-

tions. Progress was made on specifications for hydraulic turbine governors. Work also was started on speed governing specifications for internal combustion engines.

Excitation Systems. This subcommittee completed the revision of definitions of terms relating to excitation. It organized a session for the Winter General Meeting, and is sponsoring a session for the Summer and Pacific General Meeting.

Application of Probability Methods. This subcommittee organized a session for the Fall General Meeting, and sponsored the collection of outage data on high-pressure units and boilers, which are being collected by the Edison Electric Institute and analyzed by the Consolidated Edison Company of New York, Inc. The subcommittee is planning a symposium for the 1951 Winter General Meeting, on the reserve practices of hydroelectric companies. The objective of this symposium is that of divulging these practices and of stimulating the use of probability methods in hydro systems.

Hydroelectric Systems. The activities of this subcommittee during the year covered the study of outstanding developments in the field. Along these lines, the subcommittee is sponsoring a session for the Summer and Pacific General Meeting, which will include papers on underground hydroelectric plants and on factors determining the electrical design of power systems with large hydroelectric stations.

Pacific Coast. This subcommittee held two meetings during the year, one in San Francisco and one in Los Angeles, at which various problems of general interest were discussed.

Other activities of the Committee on Power Generation were:

AIEE Pittsburgh Power Conference was organized jointly with the Committees on Industrial Power Systems and System Engineering for presentation of 18 papers. Subjects ranged from general power-plant administration topics to central-station and industrial-station design and operating problems.

1950 Fall General Meeting. Three sessions are planned for this meeting on the subjects of: supervisory instruments; enclosed motor applications in power plants; gas turbines; and quick-starting of steam turbines.

Economic Evaluation of Alternate Central Station Layouts. This project will be carried by the System Economics Subcommittee as a joint project with the Committee on System Engineering.

COMMITTEE ON PROTECTIVE DEVICES

Three meetings were held by the committee, at which time the subcommittees reported on their activities and reviewed their plans for future work. The activities of the committee are carried on largely by three subcommittees.

Fault Limiting Devices Subcommittee. Application guides covering the grounding of synchronous generating systems, the methods of grounding transmission systems, and the application of ground fault neutralizers were completed during the year. These guides were presented as ACO (advance copy only) papers, and issued on a trial basis with the expectation that they would be reviewed by the AIEE membership. The working groups that prepared these guides are anxious to receive comments from anyone interested in making suggestions for their improvement. Early next year, the working groups will proceed to make final revisions.

The "Bibliography on Resonant Neutral Grounding," containing references to articles on resonant neutral grounding in the American and foreign press, was completed through the year 1938 and presented at the Fall General Meeting by title only. The bibliography covering the period 1938 to 1947 has been assembled and is scheduled for presentation by title only at the Fall General Meeting.

The Working Group on Power System Fault Limitation completed its report on methods of limiting fault currents on expanding systems, and presented it as a conference paper at the Winter General Meeting. After comments have been received, it will be brought up to date and presented formally at an AIEE meeting, and also published in the *Transactions.*

A report entitled "Field Survey of Unbalanced Charging Currents" was presented at the Fall General Meeting. This report covered the results of the survey, and indicated that the requirement that ground fault neutralizers be capable of continuously carrying 30 per cent circulating current is adequate.

One of the projects now under consideration is a survey to determine present grounding practices on industrial systems. This survey will determine if there is any accepted practice or agreement in the connection of the neutral, that is, whether the power system neutral should be grounded through a resistor, a reactor, potential transformer, ground fault neutralizer, or a combination distribution transformer and resistor. This survey will cover plants with independent generating systems as well as those which are tied in with utilities. Later, if the survey indicates that there is a need for an application guide on industrial systems grounding, a suitable group will be organized to prepare this guide. It is expected that this project will be joint with the Committee on Industrial Power Systems.

A report is also being prepared outlining the factors which determine the size and rating of grounding transformers.

Lightning Protective Devices Subcommittee. The activities of the Lightning Protective Devices Subcommittee during the past several years have been directed toward the co-ordination and unification of information relating to: performance characteristics; testing Standards; and applications of various types of lightning protective devices. Formerly, this information was incomplete, contained inconsistencies, and was scattered through several publications.

1. Performance characteristics of various types of lightning protective devices was issued for the first time under one cover in September 1949, AIEE 49-286.

2. The difficult and extensive work, particularly in the co-ordination of fundamental definitions and terminology, carried on by working groups within the subcommittee has resulted in the publication of a new and much-needed combined Protective Devices Standard *28A*, February 1950. The Standard was issued in report form and as a proposed revision to ASA *C-62* to avoid overriding an existing ASA Standard. It will be reviewed by the *C-62* Committee in the revision of the ASA Standard.

3. The subcommittee is now directing its efforts toward the completion of the "Application Guide for Lightning Protection of Substations." This guide, while it is directed particularly to the problems of substation protection, will treat important application problems of a general nature relating to the various types of protective devices. It will supplement the Performance Report and Combined Standards to provide essential lightning protection information in convenient, compact form. The Application Guide is scheduled for publication and presentation at the Fall General Meeting.

The studies which have been under way on recovery voltage characteristics of distribution systems in collaboration with the Committee on Transmission and Distribution are nearing completion. When this information becomes available, the subcommittee will reconsider the recommendation of specific recovery voltage conditions to apply during standard tests. The addition of the recovery voltage data will complete the present Lightning Protective Devices technical information program. The agenda of the subcommittee include new items relating to the protection of aerial cable, dry-type transformers, rod gap characteristics in the short-time region, and evaluation of the effects of rate of rise of surge current with respect to arrester performance.

Co-ordination of Insulation Subcommittee. This subcommittee was set up to deal with problems of insulation co-ordination which come within the scope of the Committee on Protective Devices. To date, its function has been to keep the members of the committee informed on the activities on insulation co-ordination in other Institute and ASA committees which are dealing with this subject. There are no plans for active project groups in this subcommittee at present.

COMMITTEE ON RELAYS

The committee held three meetings, and sponsored three technical sessions, at which 11 technical papers and two conference papers were presented. The technical activities of this committee were carried on through a number of project committees which are appointed to fulfill specific assignments. During the past year, four new project committees were organized. Following are the reports of the various project committees.

Generator Protection. This committee is investigating various methods of generator protection, and expects to publish a report of its findings. In May 1948, a draft of an AIEE Committee Report on Generator Protection was prepared and distributed to members of the project committee for comment. Discussion of the material in this report indicated the need for obtaining more data on present practices, and a decision was made to issue a questionnaire. A draft of the proposed questionnaire was prepared and distributed to the committee members for comment in September 1949. This draft has been revised to include the suggestions that were received, and is about ready to be issued in final form to a representative list of utility companies. The data from the replies will be summarized and used as a basis for preparing the final committee report.

Bibliography of Relay Literature. An interim report has been prepared from the relay papers presented in 1949. It is planned that

another formal report covering the past three years will be available in 1950.

Co-ordination of Construction and Protection of Distribution Circuits. This joint working group of the Committee on Relays, the Distribution Subcommittee, and the Edison Electric Institute Transmission and Distribution Committee is continuing its study of correlation of construction and protection practices on the performance of distribution circuits with regard to number of faults occurring and percentage of faults which are permanent. Thirty-eight operating companies have supplied the working group with information regarding faults on 209 circuits for the year 1949. Items being investigated include effects of type of system, size and covering of wire, configuration and spacing, and insulator and cross brace material on the number of faults occurring; and the effects of speed of clearing of faults on the percentage of faults which become permanent. It is expected that a report will be presented at the 1951 Winter General Meeting.

Standards for Power Relays. This committee completed, in 1949, a proposed revision of the ASA Standard *C-37*, American Standard for Relays Associated With Electric Power Apparatus. The Standard was approved by letter-ballot of the Committee on Relays early in 1949. It was sent to the AIEE Standards Committee in May, and was sent to the ASA *C-37* Committee on August 4. The ASA *C-37* Committee approved the Standard with minor editorial changes. The committee is in the process of gathering material on performance requirements of relays so that on the next revision a section on "Performance Standards" can be added to the existing Standard.

Insulation Levels for Relay and Control Circuits. This project committee completed its work, and a report was presented at the Fall General Meeting. The committee found that a value of 1,500 volts a-c is an adequate test voltage for the current, potential, and trip circuits of relays and associated circuits. An investigation of the standard recommended contact spacings for various types of high-speed relays showed that all of these are adequate to withstand a test of at least 1,500 volts a-c across contacts.

Sensitive Ground Protection. This committee presented its final report in the form of a technical paper at the Winter General Meeting. The report summarizes available methods for sensitive ground protection of 3-wire systems and outlines the limitations of presently available methods for the protection of systems with multigrounded neutrals.

Transmission-Line Protection. This committee sponsored three papers on transmission-line protection at the Winter General Meeting. These papers describe methods of protecting a hypothetical transmission system which involves many of the problems that are of current interest.

Electronic Relay Applications. This project committee is continuing to watch developments in the field of electronic protective relays, and is continuing its study of the application of microwave channels to protective relaying.

Relaying of Interconnections Between Industrial and Utility Generating Systems. This committee has obtained information from 32 electrical utility systems with respect to their practice of relaying interconnections with their industrial customers. Replies showed no specific trend nor recommended practice. Protective devices are applied in accordance with the individual economic or operating situation. The committee is pursuing its analysis of the problem, and plans to complete its work in 1950, with a summary of basic considerations and of suggested solutions.

Relaying Performance of Current Transformers. The activity of this committee consisted of the following: In connection with the proposal to eliminate the 2.5-accuracy classification of current transformers for relaying services, a letter was sent to members of the Committee on Relays requesting comments; only two replies were received. Information published by the Westinghouse Electric Corporation on a new line of auxiliary current transformers was reported at a meeting of the Committee on Relays.

The following are reports of the four new project committees formed this year.

Pilot Wires. The objective of this committee is to bring up to date operating experience with pilot-wire circuits used for protective relaying and transferred tripping. It is the intent that operating experience for both leased and privately owned lines will be gathered for the years 1942–49, inclusive. It is also intended to compile information relative to new or unusual pilot-wire relay schemes.

Remote Tripping Schemes. It is the objective of this committee to collect all possible information on the engineering features of all types of existing remote tripping schemes and a statement of operating experience with each. It is hoped that an analysis of these data will enable the committee to ascertain what primary difficulties are being experienced with this type of relay protection and to determine the direction in which further research is required to eliminate fundamental difficulties. A questionnaire will be circulated shortly to request data from various operating companies which have such equipment installed. It is hoped that the data will be in such form that a conference session will be possible some time in the next 12 months.

Effect of Vibration and Shock on Relays. At the request of the Committee on Relays, the project committee was formed late in 1949 to study the effect of vibration and shock on relays. The first meeting was held during the Winter General Meeting, and another is scheduled to be held during the Great Lakes District Meeting. The committee plans to study the effect of vibration and shock on relays used on electric power systems and industrial applications. It is proposed to make a survey of the industry to determine what work has been done on vibration and shock in the past, and to use such information as may be available in this study. It is proposed to make laboratory tests on various types of switchboard panels and relay mountings to determine the range of both frequency and amplitude which is most critical. This will be supplemented by a number of field tests of vibration and shock in generating plants and substations. From this information, the committee proposes to prepare a paper offering a suggested guide, which should be useful to the industry in designing and applying protective relays to avoid difficulty from shock and vibration.

Project Committee on Relay Test Methods. This committee held one meeting, at which it was decided that the committee would attempt to collect data from all available sources on portable field testing equipment suitable for testing the majority of the more complicated types of relays. The data will then be reviewed by the project committee and one or two of the most efficient sets of equipment selected, possibly improved by suggestions, and this information will be presented to the Committee on Relays. Along with the description of any test equipment, there will be submitted general instructions on its applications and use. Some data have been furnished by committee members. However, since some very efficient equipment may not otherwise come to their knowledge, all members of the Committee on Relays will be asked to submit their ideas and recommendations.

Joint and Associated Projects. Through representation, the committee participates in the activities of the Instrument Transformer Subcommittee of the Committee on Transformers, with special attention to the relaying performance of current transformers and the transient performance of capacitance potential devices. Close co-ordination has been maintained with activities of the Committee on Carrier Current on items of joint interest.

COMMITTEE ON ROTATING MACHINERY

A report on the activities of each subcommittee is given in the following.

Single-Phase and Fractional-Horsepower Subcommittee. Review is in process of the test code for single-phase motors, and an attempt will be made to correlate with the Master Test Codes, AIEE *550* and *557*. Since small d-c motors are now officially within the scope of the committee, activity will be pushed along this line. A technical conference is planned for applications of fractional-horsepower motors, and may be held in Dayton in the spring of 1951.

D-C Subcommittee. Culminating more than two years of concentrated activity, including two committee papers on the subject, the subcommittee has now submitted a definite proposal for revision of Table I of ASA *C-50*, covering limiting observable temperature rise of d-c rotating machines. The proposal is based on data amassed from commercial testing and from a group of co-operative research tests, and features expansion of use of the resistance method as an alternate to a thermometer, as well as inclusion of Standards for short-time rated machines. The subcommittee is now active on the matter of d-c machine short-circuit currents.

Synchronous Machinery Subcommittee. An active technical paper program is bearing fruit. A review is being made of telephone influence factor and deviation factor.

Induction Machinery Subcommittee. A test code revision is being completed. An active program is being followed on technical papers.

Insulation Subcommittee. The subcommittee has concluded and the Standards Committee has accepted a revision of AIEE Standard *43* on insulation resistance testing. The subcommittee is being expanded to cover insulation practices as well as insulation resistance.

Test Code Co-ordinating Subcommittee. The subcommittee is working with other subcommittees and with ASA on revision and co-ordination of test codes, the dominant theme being proper use of the Master Test Codes *550* and *551* where possible to avoid duplication and mass of information.

Future Meetings. A symposium on induction, and possibly synchronous, machinery for oil well applications is being considered for the Fall General Meeting.

COMMITTEE ON SUBSTATIONS

The status of the projects on which work is in progress in the subcommittees and working groups of this committee is as follows.

Automatic and Supervisory Control Subcommittee. Besides collecting material for use in the next revision of American Standard *C37.2*—1945 for Automatic Station Control, Supervisory, and Telemetering Equipments, this subcommittee is studying rectifier reclosing control problems, standardization of annunicator systems, and the relative merits of insulating versus grounding d-c switching structures.

Distribution and Conversion Substations Subcommittee's study of the relative merits of bus voltage regulation versus feeder voltage regulation has resulted in the preparation of a paper by one of its members for the Middle Eastern District Meeting, in October, with a group of related papers to follow at a later meeting. Comparative studies of circuit breaker versus reclosing fuse application will shortly result in the preparation of a paper by another member of this subcommittee. Those working on the outdoor substation lighting problem have been in touch with the IES committee that is engaged in similar activities.

Transmission Substation Subcommittee met at the end of January to review progress made in the study of its assigned problems, including the basic structural design of substation structures for 110 kv and above, and safety considerations in substations.

Working Group on Basic 1-Line Diagrams was recently formed from personnel from both the Distribution and the Transmission Substation Subcommittees to review existing practices and classify current opinions regarding suitability of various fundamental connection schemes for substations. The work of this group will serve as the basis of further activity on the part of its two parent subcommittees.

Working Group on Device Function Numbers has been requested to recommend what minor changes in the present device function numbers should be made, after the returns from their nationally circulated questionnaire showed 78 per cent favored no changes.

Working Group on Rectifier Switchgear is devoting some attention to the formulation of equivalent constants for rectifiers, for use in calculating board studies, and to a study of the voltage surge problem.

Working Group on Substation Grounding Practice has prepared a 3-page questionnaire for widespread circulation, and has submitted this to all the main committee members for comments by mail.

Committee Meetings. In addition to subcommittee and working group meetings, meetings of the main committee were held on June 20, in Swampscott, on October 21, in Cincinnati, and on February 1, in New York. A meeting of the main committee was also tentatively scheduled for June 14, in Pasadena.

COMMITTEE ON SWITCHGEAR

AIEE Standard *20A*, which was published for trial use, is still on a trial basis. Further action on it is held up because of controversy over temperature rise clauses. It is hoped that data will be available shortly so that this point can be cleared up.

The proposed Standard *22A* was published in November 1949, and covers "Air Switches, Insulator Units, and Bus Supports, Combined With Air Interrupter Switches." It is now on a trial basis.

Subcommittee on Switches, Fuses and Insulators is actively working on a revision of Standard *25* for fuses above 600 volts.

Standard *27*, covering "Switchgear Assemblies," which had been recommended to the Standards Committee during the previous year, was returned last summer to the Committee on Switchgear, which, in turn, referred it back to the Subcommittee on Switchgear Assemblies. Objections from a number of sources to the temperature rise clauses have held up this Standard until the point can be clarified. During this waiting period, the subcommittee has been actively making minor revisions.

Proposed Standard *50* for "Automatic Circuit Reclosers for A-C Distribution Systems" was published in September of 1949 for a 1-year trial.

Circuit Breaker Subcommittee is actively working on the "Test Code for Power Circuit Breakers," and good progress has been made on the "Code for Low-Voltage Air Circuit Breakers." The "Guide for Application of Low-Voltage Air Circuit Breakers," which was prepared last year and presented at the Summer General Meeting, was published in *Electrical Engineering* and in pamphlet form during the summer. The subcommittee is also very active on the revision of the Standards for "A-C Power Circuit Breakers," "Methods for Determining the RMS Value of a Sinusoidal Current Wave and a Normal Frequency Recovery Voltage," and "Rated Control Voltages."

The Joint Subcommittee on Out-of-Phase High-Voltage Switching rendered its report, which was submitted by mail to the members of the Switchgear Committee. The Switchgear Committee, by letter-ballot, approved the report, recommended the discharge of the subcommittee, and recommended that the report be printed.

The committee sponsored a session at the Summer General Meeting, and also one at the Winter General Meeting.

COMMITTEE ON SYSTEM ENGINEERING

This committee was active at all three general meetings. The same subcommittee setups were continued into what is now the third year since this committee was formed. There was a realignment of personnel at the start of the year, with about one-fourth of the membership new members to stimulate the thinking in the committee and to give additional representation in several of the cities in the central west and southwest areas of the country.

It continues to be the policy of this committee to confine its program to one topic at each technical session and develop it fully as material is available. Because of the broad-gauged nature of the work, this has proved a more satisfactory approach than that normally followed in talking about detailed apparatus problems and their utilization which would fall to more specialized committees. A total of five normal papers and 13 conference papers were presented.

There were two committee meetings during the year, one each at the Fall and Winter General Meetings, and a full 1-day meeting in Chicago during May. The meetings held in connection with the general meetings were largely devoted to a review of the program to be followed at subsequent meetings. The meeting in Chicago covers a more adequate discussion of engineering aspects of the problems in addition to the review of the committee programs for future meetings. The success of this meeting will be weighed in determining whether it should be the annual policy of this committee.

System Planning Subcommittee. This subcommittee is sponsoring a group of five companion papers at the Summer and Pacific General Meeting, which will discuss design features and long-range planning of the systems in the Pacific Southwest. The extensive use of high voltage transmission and the co-ordination of hydro and steam plants in that area will stimulate discussion of better planning practices. This subcommittee also sponsored several papers dealing with the use of the calculating board. This well-established tool for assistance in system planning is universally used, but new techniques for simplifying the application were described at the Fall General Meeting, with extensive interest as a companion to an earlier presentation the previous winter.

System Economics Subcommittee. This subcommittee considers both the economics of system operation and economics of over-all system engineering. In the first category, it has sponsored a paper which described the use of the calculating board as an operating tool in determining most economical loading of generating stations. The committee is now actively investigating problems associated with economics of interconnections, economics of high-cost high-efficiency generating capacity versus lower cost and lower efficiency capacity, rehabilitation of old plants, use of gas turbines for peak load, and economical sizes of units and power plants. Evaluation of system losses as a component of system capacity requirement is being studied also.

System Operations Subcommittee. This subcommittee sponsored a conference session at the Winter General Meeting, devoted to the subject "Operation of Systems at Leading Power Factor." The high power factor of systems now being experienced during light load periods due to installation of high-voltage underground and overhead transmission systems and extensive use of static capacitors has forced a review of the original concept of system operation requiring operation at substantial lagging power factor. Conference papers were presented by both generator manufacturers and power-system representatives, discussing the theory of operation at leading power factor and of a few cases of practical experience cited. The desirability of using automatic voltage regulators extensively in this operation was pointed out. A few companies had considered the necessity for loss of field relays in this connection to pre-

vent the sustained reactive demand and low voltage which results from loss of field. It was the opinion of the subcommittee that the conference did not develop any papers which could be presented on a formal basis, but the conclusion was reached by the speakers that leading power factor operation could be entered into on a moderate scale as the necessary safeguards are provided.

This subcommittee is studying the problem of adequate station electric auxiliaries in power stations during periods of system trouble. Several recent shutdowns of power systems have pointed out the need for studying this problem and reviewing operating procedures.

System Control Subcommittee. Although this subcommittee has not been active during the year, it is now studying two basic problems: the use of automatic load control on high-efficiency versus low-efficiency capacity; and the most desirable rate of load change on different types of generating equipment.

Joint Subcommittees. The subcommittee on out-of-phase high-voltage switching completed its study and presented a report which was accepted.

The Probability Subcommittee is active. It presented a second report at the Fall General Meeting, and now is extending its study to include more recent data on outages of turbine generator units operating at 700-pound or higher and hydro units.

The Committee on System Engineering was one of the sponsors of the Power Conference in Pittsburgh, Pa. It co-operated with the Committee on Industrial Power Systems in the program for April 20, and it presented two papers discussing problems associated with utility power-system supply to industrial plants.

COMMITTEE ON TRANSFORMERS

This committee consists of 33 members operating 15 working groups. In addition, 42, mostly members of the Institute, assist in the working group activities.

The following report gives changes in the status from that reported in last year's activities.

Co-ordinated Study of Life of Transformer Insulation Working Group. Apparatus and technique for this subject is all well developed, but some difficulty has arisen in obtaining satisfactory test samples. All of this work is limited to the pilot tests, which will form the basis for the final aging program.

Joint Subcommittee on Instrument Transformers. The subcommittee has a number of active subjects under discussion. "Application Guide for Grounding of Instrument Transformer Secondary Circuits and Cases" has been issued as ACO paper 50-65.

Subcommittee on Papers. This subcommittee has been responsible for obtaining, so far this year, 20 technical papers, and three conference papers. For the Summer and Pacific General Meeting, two sessions have been arranged.

Operating Guides for Regulators Working Group. Technical paper 49-228 has been referred to the Standards Committee for approval as a revision of ASA *C57.35*, dated 1948.

Short-Circuit Thermal Ratings of Induction and Step Regulators Working Group. The work on this assignment is progressing, but, at the present moment, is not ready for final decision. This subject deals primarily with the revision of ASA *C57.35*, and includes an explanation of paragraph 15.050 in connection with reclosing devices.

Magnetization Characteristics of Transformers Working Group. The scope of this assignment remains unchanged, and all the committee can report is progress.

Revision of Dielectric Tests Working Group. The same problems confront this working group as outlined in last year's report. Additional pressure is being exerted to bring up to date all impulse testing technique.

Guides for Operation and Maintenance of Dry-Type Transformers With Class-B Insulation Working Group. A report on the activities of this subcommittee has been submitted to both the Edison Electric Institute and the National Electrical Manufacturers Association for comment and review. The committee now awaits final comments of the National Electrical Manufacturers Association's Standards Committee before proceeding with any further changes to the Guides.

Co-ordination of Insulation Working Group. The work of this committee is progressing satisfactorily. Additional requests for information have been received.

Electronic Power Converters Working Group. This is a 1-man committee acting as liaison representative between the Committee on Electric Power Converters and the Committee on Transformers.

Methods of Making Temperature Tests on Transformers Working Group. Technical paper 50-99 has been issued as a preliminary report dealing with temperature tests. The committee is completing a report which will be a revision of ASA *C57.22.100*.

Power Factor Measurements Working Group. This originally was a 1-man committee, but has now been augmented with an additional member. The committee expects to complete this report by the end of the term.

Audible Noise in Transformers Working Group. A number of technical papers have appeared due to the activities of this group. Work has not been completed to a point where a report can be issued.

Hot-Spot Temperature Rise of Class-B Reactors Working Group. This is a new group and will cover Class-*B* reactors not now included in Table *C57.11.021*.

Permissible Maximum Oil Temperature in Service Working Group. This committee is working on the permissible maximum oil temperature of transformers in service. This subject is a study to determine whether it is permissible to operate sealed-type transformers in excess of the 100-degree-centigrade limitation in the present Guide *C57.32*.

COMMITTEE ON TRANSMISSION AND DISTRIBUTION

The general plan of operating the committee during the past year has been to continue the five subcommittees dealing with subjects within the scope of the main committee, and assign to them additional subjects of interest and importance in the transmission and distribution field as they arise, either from suggestions of committee members or others outside the committee. It has been the aim of the committee to clear all valuable and important information to Institute members by technical or conference papers, when any work has progressed to a point where it is of significant value. No attempt has been made to enhance the committee prestige by soliciting papers merely to get volume, but rather an effort has been made to obtain high-grade well-digested material for technical papers to record the progress of the art, promote constructive thinking, and study and investigate engineering features within the committee scope.

In the distribution field, a study is being made jointly with the Edison Electric Institute to obtain records of operating experience on distribution lines. This project, mentioned last year, is still in progress. The subject of distribution system economics is also being given attention.

In the lightning field, a laboratory study on the lightning strength of wood-pole lines in the subtransmission range is progressing. It is expected co-ordination of this work with field experience will be of value.

The predetermination of the lightning performance of transmission lines, which has been studied from a theoretical point of view, is reaching fruition in a committee report planned for the Summer and Pacific General Meeting. The Lightning Bibliography, which takes the place of the proposed second volume of the Lightning Reference Book, has been completed, and is expected to be published and made available for distribution in the summer of 1950. Two projects affecting transmission-line operation are progressing satisfactorily. One relates to a general survey of the causes of all transmission-line outages, and the other is a study of system recovery voltage.

After the co-ordinated technical session on capacitors at the Fall General Meeting, where an extensive discussion developed on capacitor operation, further study has been undertaken, mainly directed to capacitor temperature, tank corrosion, and short-time capacitor voltage ratings. A bibliography on this subject is in the course of preparation. Further public presentation on this subject is tentatively planned for 1951.

The series capacitor has been given some consideration, with regard to its application on high-voltage lines, as well as on low-voltage lines, to prevent voltage flicker.

In the conductor field, a study is being made on higher permissible conductor current loading, damage to conductors from vibration, and means of alleviating the trouble. A symposium on this latter subject is being planned for the Fall General Meeting.

A number of other subjects being dealt with in subcommittees have not yet reached the stage where present publicity would serve any useful purpose. During the year, the committee sponsored papers, solely or jointly with other committees, at general meetings, and at one District Meeting. It has offered papers within its field for the Middle Eastern District Meeting. For the Winter General Meeting, a session on technical features of high-voltage transmission is being arranged.

During the past year, technical papers passing through committee review have included those on power capacitors, recovery rates of voltage on distribution systems, arc extinction characteristics of gaps, insulator contamination and corrective measures, primary network systems, corona and radio-influence effects, distribution system planning, and operational characteristics.

For the 1950 Great Lakes District Meeting, three papers were offered, dealing with plan-

ning subtransmission and distribution systems, right-of-way brush control, and protection against conductor burndown.

For the Summer and Pacific General Meeting the committee is sponsoring papers on corona features, economics and lightning performance of high-voltage transmission lines, as well as other papers dealing with insulation co-ordination and interrupting ability of horn gaps.

COMMITTEE ON BASIC SCIENCES

The committee sponsored one session each at the Summer General Meeting, and the North Eastern District Meeting; a total of eight papers were presented at these meetings. It also sponsored a session on voltage induction during the Fall General Meeting, in the course of which five conference-type papers were presented. The committee had meetings at the Summer General Meeting and the Winter General Meeting, the prime object of which was the review of the activities and plans of the six subcommittees of the Committee on Basic Sciences, as well as discussion of items of general interest, such as the standardization of voltage and current notation and the nomenclature pertaining to sinusoidally varying alternating values.

Perhaps the most valuable service rendered to the members of the Institute by the committee is through the co-ordination and sponsorship of the work of its six subcommittees, all of which were very active during the past year; the symposia arranged by several of these subcommittees enjoyed a surprisingly large attendance, proving that the subject matter was of great interest to electrical engineers.

Reports on the activities of the subcommittees follow.

Subcommittee on Electrical Properties of Solids and Liquids. Because of the rapidly increasing use of semiconductor devices in electrical engineering, this subcommittee has been unusually active in the past year. A symposium on electrical properties of semiconductors and the transistor was held at the Summer General Meeting. Four articles covering the subject matter of the symposium appeared in *Electrical Engineering*, and have been assembled in a pamphlet. A second symposium of seven papers on "dielectrics" was held at the Winter General Meeting. These additional symposia were intended primarily for the nonspecialist engineer. For engineers who are specializing in semiconductor devices, a Conference on Electron Devices is to be held at the University of Michigan in June. This is jointly sponsored by the IRE and several AIEE committees.

Subcommittee on Energy Sources. The subcommittee sponsored its fourth Conference on Energy Sources at the Winter General Meeting. Three papers, dealing with recent developments in the field of electric batteries, were presented. The subcommittee is arranging for publication, in pamphlet form, of the first 14 papers presented since the formation of the subcommittee in 1946.

Subcommittee on Electric Circuit Theory. This subcommittee sponsored a conference on applications of conformal mapping in electric circuit analyses at the Fall General Meeting. Three papers were presented. Members of the subcommittee have been generous in devoting time to review the unusually large number of papers in electric circuit theory submitted to the Institute in recent months.

Subcommittee on Applied Mathematics. The subcommittee sponsored two conferences on applied mathematics, one at the Summer General Meeting and another at the Winter General Meeting. The subcommittee also expects to participate in the International Conference of Mathematicians, to be held in Boston, Mass., August 30 to September 6, 1950. The subcommittee has proposed to the Committee on Basic Sciences a new plan of activity, a full description of which was published in the May issue of *Electrical Engineering* under "Committee Activities." Briefly, the plan consists of inviting prominent mathematicians to become members of this subcommittee and enlisting their co-operation in solving engineering problems which would be submitted by the members of the Institute. Approximately ten prominent mathematicians have already signified their willingness to participate in this venture. The co-operation of the membership of the Institute in this project will determine to what extent the plan will be successful. The subcommittee is corresponding with the chairmen of various technical committees in the hope that it can stimulate interest in this project and obtain the problems in the fields of these committees, which lend themselves to mathematical treatment.

Subcommittee on Electrical Properties of Gases. This newly formed subcommittee held two meetings in 1949, one in April and one in November, both of which were attended by the full membership. Both of these meetings were concerned primarily with plans for a session on the electrical properties of gases at the 1950 Winter General Meeting. This session, the first organized and sponsored by this subcommittee, was held as scheduled; papers by four outstanding speakers were presented, and the attendance was very gratifying. The papers are scheduled for publication in *Electrical Engineering* as a series in succeeding issues. The members of the subcommittee held another meeting during the Winter General Meeting. Encouraged by the interest shown in the subject as shown by the large attendance, a similar session on the electrical properties of gases during the 1951 Winter General Meeting is planned.

Subcommittee on Magnetics. The subcommittee arranged for a symposium for the Winter General Meeting, consisting of seven papers on various subjects connected with magnetics, and a moving picture showing the movement of domain boundaries during magnetization. The attendance was exceedingly good, reaching 400 on Tuesday afternoon. This indicated a continuing interest in the subject, and another symposium is planned for the 1951 Winter General Meeting.

COMMITTEE ON COMPUTING DEVICES

The intense activity in the field of large-scale computing devices which arose following the end of the war is showing results in a steadily increasing number of papers in this field. There is intense competition among large laboratories in a development race which remains largely under cover. However, a tremendous range of applications is being investigated, and the possibility of using electronic computers in place of, or in addition to, present business machines seems attractive. There have been investigations of the possibility of using large-scale computers in place of a-c calculating boards and at the same time there have been improvements in the use of a-c calculating boards which have increased their efficiency appreciably.

In the field of large-scale computing itself, problems continue to grow in proportion as the ability to solve them grows, and there appears pressure for types of work which only a few years ago would not have been contemplated. The realization of the power of computing devices and the ease with which they can be manipulated has led to the growth of many special-purpose devices. As the principles become better known, it seems that the field of large-scale computers will be a well-defined engineering field, and a large part of the technical work will fall within electrical engineering.

Not much has been said with regard to continuous variable computers, but these are widely used and are being continuously improved. One reason for less information concerning them is that many applications are in the military field.

The Committee on Computing Devices held one session at the Winter General Meeting and at that time laid plans for the remainder of the year. These are resulting in two sessions at the Summer and Pacific General Meeting, one of which is on the application of large-scale computers in aircraft development, a possible session at the Fall General Meeting on applications of large computers to the petroleum industry, a session at the North Eastern District Meeting, a session at the coming Middle Eastern District Meeting, in October, and at least two sessions at the 1951 Winter General Meeting.

A special activity of the committee is the preparation of a bibliography covering the field of computers. This work is to be done in co-operation with a corresponding IRE committee, and it is hoped that a publication will result.

The committee has two subcommittees, one on continuous variable computers and one on digital computers. The work of these subcommittees has been devoted largely to the procurement of papers and the organization of those sessions which have been held or are contemplated.

There is an interesting side line in the field of the committee, in that many basic problems in the field are associated with others in the fields of communications, switching, control, and so forth. In this connection, not many persons realize that what is practically an entirely separate system of algebra has been built up especially for use in the computing device and associated fields. The committee is endeavoring to obtain an authoritative paper on this aspect of its work to see whether there is sufficient interest among electrical engineers to warrant presenting new developments of this type before the AIEE.

COMMITTEE ON ELECTRONIC POWER DEVICES

The activities of the committee during the year consisted mainly in completing projects previously initiated and encouraging papers on new developments and applications. Some new projects are also under consideration. Plans for the year were outlined at a meeting of the Administrative Subcommittee held September 12, 1949, in Pittsburgh, Pa. A meeting of the full committee was held on February 1, 1950, in New York. Meetings were held also by some of the subcommittees during the year.

The progress on the various projects is summarized in the following reports.

"*Survey on Operation of Mercury-Arc Rectifiers.*" The Subcommittee on Electronic Converter Applications has been making a survey on operation of mercury-arc rectifier installations. Questionnaires requesting operational data have been sent to rectifier users. A preliminary report on the results of the survey was presented at the Fall General Meeting. The final report will be presented at the Summer and Pacific General Meeting.

"*Report on Inductive Co-ordination on the D-C Side of Rectifier Installations.*" A working group of the Subcommittee on Applications is preparing a report on inductive co-ordination aspects relating to the d-c side of rectifier installations. A second draft of the report has been written and it is now expected to have the report completed in time for presentation at the Winter General Meeting.

"*Protection of Electronic Power Converters.*" A working group consisting of members of the Subcommittee on Electronic Power Converter Circuits and representatives of the Committee on Substations have been engaged in the preparation of a report on "Protection of Electronic Power Converters." This report is devoted primarily to the problem of protection of power rectifiers of the sizes and types usually encountered in railway, electrochemical, and general industrial applications. The report was presented in two parts at meetings in January and October 1949. These have been revised and combined into a single report for final presentation at the Summer and Pacific General Meeting and publication in the *Transactions*.

"*Bibliography on Electronic Power Converters.*" A bibliography covering the years from 1903 to the end of 1947 has been published by AIEE. The Subcommittee on Papers and Speakers reported no other activity.

"*Standards for Hot-Cathode Power Converters.*" The Subcommittee on Hot-Cathode Power Converters has been transferred from the Committee on Electronics to the Committee on Electronic Power Converters, in order to facilitate co-ordination with the pool cathode group. This subcommittee is engaged in the preparation of Standards for hot-cathode power converters. A set of definitions has been adopted by the subcommittee, and is being circulated in the main committee for comments.

The activities of the subcommittees and working groups, other than those reported on the foregoing projects, were carried on as follows.

Subcommittee on Electronic Power Converter Circuits is soliciting papers on surges, fault currents, protective gear, and rectifier power factor.

Subcommittee on Rectifier Transformers is soliciting papers on transformer noise and surge protection.

Subcommittee on Rectifying Devices is co-operating with other committees working on Standards for pool tubes, and is keeping the members of the main committee informed on such activities.

West Coast Subcommittee is co-ordinating AIEE activities relating to electronic power converters in that region.

Rectifier Standards. A working group has been organized to review the development of world standards on rectifiers, and to keep the members of the main committee informed on such activities.

Conference on Rectifier Cooling Systems. The committee is planning to hold a conference on cooling and corrosion problems relating to rectifier cooling systems during the fall in 1950.

COMMITTEE ON ELECTRONICS

The sponsorship of 2- or 3-day conferences relative to specific work areas in electronics has been one of the important continuing contributions of the committee for the past several years. Thus, the Second Annual Joint Conference on Electronic Instrumentation in Nucleonics and Medicine was held in New York, October 31, November 1–2, 1949. This was sponsored jointly by the Committees on Electronics, Nucleonics, and Instruments and Measurements within the AIEE, and the Nucleonics Studies Committee of the IRE. The conference was fully as successful as its predecessors, and plans have been formulated for a similar conference in the fall of 1950.

A 3-day Symposium on Improved Quality Electronic Components will be held in Washington early in May 1950, under the sponsorship of the AIEE Joint Subcommittee on Electronic Instruments, the Institute of Radio Engineers, and the Radio Manufacturers' Association. This is the third annual spring conference in a general series dealing with various aspects of engineering problems involved in the industrial applications of electronics.

The Subcommittee on Electron Tubes is sharing with the IRE Committee on Electron Tubes and Solid State Devices the sponsorship of the annual Conference on Electron Devices, to be held at the University of Michigan, Ann Arbor, Mich., June 22–23, 1950. This conference deals, on a completely informal basis, with new discoveries and projected methods and techniques in research and early development work on electron tubes and semiconductor devices.

Meetings of the committee were held in Swampscott in June 1949, at the National Electronics Conference in Chicago in September 1949, and at the Winter General Meeting.

The National Electronics Conference, held annually in the fall, in Chicago, is a very large middle-western forum for the presentation of papers of electronic interest, incorporating an extensive manufacturer's display of electronic instruments and new products; the *Proceedings* of the National Electronics Conference, published annually, contains in complete form the papers presented at the NEC.

It has become the policy of the Committee on Electronics to give substantial support to the NEC. Thus, during the past year, the chairman of the committee has served actively as the AIEE representative on the NEC Board of Directors, and various members of this and other AIEE committees have assisted in building greater strength into the industrial electronics part of the annual NEC program.

As a part of the continuing effort to bring to AIEE membership early reports on new electronic developments, various specific areas of work have been emphasized by holding three conference sessions at the Summer General Meeting and four at the Winter General Meeting.

A full program of papers of electronic interest is assured for the Summer and Pacific General Meeting, and for the Fall General Meeting.

The changes in the technical subcommittee structure during the year have been: the addition of Subcommittees on Electronic Systems Engineering and on Liaison With Electronic Heating, the transfer of the Subcommittee on Hot-Cathode Electronic Power Converters to the jurisdiction of the Committee on Electronic Power Converters, and the transfer of the Subcommittee on Electronic Aids to Medicine to the status of a joint subcommittee, sponsored also by the Instruments and Measurements Committee. At present, there are 19 subcommittees and two joint subcommittees.

With active advice and counsel from the chairman of the Subcommittee on Electronic Standards, there has been substantial progress towards Standards formulation in the following areas: X-Ray Tubes, Apparatus, and Applications; Electron Tubes, particularly High-Vacuum Tubes, Cathode-Ray Tubes, Gas-Filled Tubes, Phototubes, and Mercury-Pool Tubes.

COMMITTEE ON INSTRUMENTS AND MEASUREMENTS

The committee had a very interesting and active season. The personnel was changed so that 38 members were carried over from last year's roster, and 18 new members replaced 14 retiring members of last year's committee. Two vice-chairmen were named to assist in the operation of the committee, one for the East, and one for the West. The duties of the vice-chairman for the East were to procure and process papers originating in cities bordering on the Mississippi River and east of that river for technical sessions, and to arrange all technical programs sponsored by the committee at general or District meetings held in the afore-mentioned area. The duties of the vice-chairman for the West were similar except that he covered the area west of the Mississippi. The purpose of this arrangement was to ensure that instruments and measurements activities will be ably represented at all general and District meetings.

A committee meeting was held on September 19 to plan the year's program. A luncheon meeting was held January 31 to further the committee activities. This meeting was attended by 35 committee members and nine guests, including President Fairman, who spoke on joint activity of AIEE with other societies. A meeting is planned for May, in Philadelphia, and one will be held at the Summer and Pacific General Meeting.

The changes in the committee structure and the activities of the continuing subcommittees are reported as follows.

Changes

1. *Subcommittee for Revision of ASA's C-39* has been discontinued, since this work has been completed.

2. *Subcommittee on a Master Test Code for Resistance Measurements* has been discontinued, since the test code has been completed.

3. *Joint Subcommittee on Servomechanisms* has been promoted to full committee status.

4. *Subcommittee on Co-operation With the Instrument Society of America* has been named a standing subcommittee, since it is expected that the AIEE will continue to participate in the yearly instrument conference of the ISA.

Two interesting technical sessions were

arranged by this committee at the September 1949 conference held in St. Louis.

5. *Subcommittee on Electrical Aids to Medicine* has broadened its scope and is now a Joint Subcommittee of the Committees on Instruments and Measurements, Electronics, and Therapeutics.

6. *Subcommittee on Organization* was set up to study the relationship of the Committee on Instruments and Measurements to other technical committees and to make recommendations for future activities of the Committee on Instruments and Measurements.

7. *Joint AIEE–IRE Committee on High-Frequency Measurements* has been set up to handle jointly technical conferences, Standards, and definitions in this particular field. The AIEE representatives on this committee will form the Subcommittee on High-Frequency Measurements to act on matters pertinent to the AIEE.

8. *Subcommittee on Industrial Spectroscopy* has been formed, and will handle matters relating to design and characteristics of instruments and measurements pertinent to the field of industrial spectroscopy. It will promote technical sessions covering new or improved practices and determine Standards and definitions for this particular field. The final scope will be determined when the subcommittee becomes better organized and has its first meeting. One of its first activities was to schedule an informal conference session at the Winter General Meeting.

9. *Subcommittee on Master Test Code for Power Measurements* has been formed, and will draft a master code as required throughout the field of electrical engineering. It will be similar in construction to the Master Test Code for Resistance Measurements and the Master Test Code for Temperature Measurements which have been completed recently by the Committee on Instruments and Measurements.

Continuing Subcommittees

1. *Subcommittee on the Revision of Standard 4* (Measurement of Test Voltage in Dielectric Tests) is currently awaiting the prosecution of further tests and test data formulation from several commercial, industrial, and government laboratories. Completion of this work, particularly in the field of short-time impulse measurement, is awaited to assist the resulting work of standardization projected by this subcommittee.

2. *Subcommittee on Watt-hour Meters* issued a report entitled "Errors in Watt-hour Meter and Electrical Indicating Instrument Readings Caused by Harmonics in the Wave Form of the Supply Voltage," on January 24, 1950, for informal release to the New England Power Service Company and others technically interested. The subcommittee has tentatively established for itself the following fields of activity:

(a). Preparation of a bibliography on the subject of watt-hour meters and associated fields such as demand meters.

(b). The study of metering of loads of very short duration such as welders.

(c). A study of the performance of watt-hour meters on high frequencies, 400 cycles and above.

(d). A study of the testing of calibrating techniques for the watt-hour meter.

(e). The effect of temperature and the resulting errors when testing watt-hour meters out of doors at light loads.

Item *a* will be actively processed. Concurrently, the suitability of the other items will be appraised.

3. *Subcommittee on Definitions* still has under consideration the second draft of the definitions of Group 30, Instruments, Meters, and Meter Testing, which are being prepared by the *C42* Subcommittee, Number 6. Final approval of the second draft should be completed shortly.

4. *Subcommittee on Electrical Tests on Dielectric Measurements in the Field* is making a survey to determine current practices in field testing of dielectrics. A conference session on insulating oils was sponsored by this subcommittee during the Winter General Meeting.

5. *Subcommittee on a Master Test Code for Temperature Measurements* is revising Section 2 of the test code, AIEE *551*, in accordance with a request of the Standards Committee to make it identical with the corresponding section of AIEE Number *1*.

6. *Subcommittee on High-Frequency Measurements* sponsored a technical session at the Winter General Meeting.

7. *Subcommittee on Marking Varmeters and Related Instruments* has completed its survey with regard to practices in marking varmeters, and a report is in progress.

Joint Subcommittees

1. *Joint Subcommittee on Instrument Transformers* has been assisting actively in preparation of Standards and held a very successful technical session at the Winter General Meeting.

2. *Joint Subcommittee on Telemetering* has continued active collaboration with the National Telemetering Forum through attendance at NTF meetings and an increasing cross-membership. This subcommittee has accepted the responsibility of completing a "Glossary of Radio Telemetering Terms," which had been started by the Instrument Research Division of NACA. This joint subcommittee held a Technical Conference on Telemetering, jointly sponsored by the NTF in Philadelphia, May 24–26.

3. *Joint Subcommittee on Electronic Instruments* arranged a technical session on miscellaneous electronic instruments for the Winter General Meeting, and, with the assistance of the Joint Subcommittee on Telemetering, a technical session on radio telemetering for the 1949 Summer General Meeting. This joint subcommittee represented the AIEE in sponsoring jointly with IRE and the Radio Manufacturer's Association a Conference on Improved Quality Electronic Components, May 9–11, 1950, in Washington, D. C. Work has continued on the formulation of standardized forms for the specification of vacuum-tube voltmeters and for cathode-ray instruments, including a glossary of pertinent terminology.

4. *Joint Subcommittee on Nucleonic Instruments*, working with the Joint Subcommittee on Electrical Aids to Medicine and the IRE, sponsored the Second Annual Joint AIEE–IRE Conference on Electronic Instrumentation in Nucleonics and Medicine, held in New York, October 31, November 1–2, 1949. Plans already are under way for a 1950 conference. This subcommittee also sponsored a session on nucleonic instruments for the Winter General Meeting.

The Committee on Instruments and Measurements has been active in other fields through its representation on other committees of the AIEE, American Standards Association, and The American Society of Mechanical Engineers. In addition to the previously mentioned nine technical sessions, which were sponsored by its subcommittees, the committee also sponsored two sessions at the Summer General Meeting, one session at the Fall General Meeting, one session at the Winter General Meeting, and one session at the North Eastern District Meeting. This makes a total of 14 technical sessions for the 1949–50 season.

COMMITTEE ON METALLIC RECTIFIERS

During the past year, full meetings of this committee were held on June 24, in Swampscott, and on January 31, in New York.

The chief accomplishment of the year has been the preparation of Standards for Metallic Rectifiers, which include standard definitions and testing standards. The last revision of these Standards is in practically its final form.

At the January meeting, a new Subcommittee on Miniature Rectifiers was organized to take care of the special requirements of this type of equipment. At the same meeting, another subcommittee was set up for the purpose of developing necessary technical information which will be useful to users of metallic rectifiers and which will standardize many of the commonly used circuit ratings and other design or application factors.

Plans are being made for a conference session on metallic rectifiers at the Summer General Meeting in 1951.

COMMITTEE ON NUCLEONICS

The committee held two meetings during the year, one in connection with the Summer General Meeting, and the other during the Winter General Meeting.

The Subcommittee on Safety and Health Protection Against Radiation has been dissolved, and its functions transferred to the Joint Subcommittee on Nucleonic Instruments. A new Subcommittee on Nuclear Machines is in the process of being set up. Four subcommittees of this committee are now as follows: Joint Subcommittee on Nucleonic Instruments (Joint with the Committee on Instruments and Measurements), Subcommittee on Isotopic Tracers, Subcommittee on Nuclear Physics, and Subcommittee on Nuclear Machines.

The committee activities were directed toward bringing nucleonic information to the Institute membership. The committee sponsored or will sponsor conference sessions on nucleonics at the following meetings:

Summer General Meeting, four papers covering nucleonic instrumentation, sponsored by Subcommittee on Nucleonic Instruments.

Winter General Meeting, five papers covering nucleonic instrumentation, sponsored by Subcommittee on Nucleonic Instruments.

Joint AIEE/IRE Special Technical Conference on Electronic Instrumentation in Nucleonics and Medicine, New York, October 31, November 1 and 2, 1949, with 27 papers. A joint committee is preparing for a similar conference in October 1950.

The committee will be a joint sponsor of two sessions at the Summer and Pacific General Meeting, one with the Committee on Electronics and the other with the Committee on Electronic Power Converters.

A meeting of the Atomic Energy Commis-

sion Ad Hoc Committee on Technological Information for Industry was attended. This work is now being carried on by C. S. Rich, Editor, *Electrical Engineering*.

The committee has also co-operated in the review of the various nucleonics glossaries now nearing completion under the auspices of the National Research Council.

COMMITTEE ON THERAPEUTICS

Activity of this committee has consisted of review and approval for publication of a technical paper entitled "Electrical Instrumentation in Medical Research" by J. Malvern Benjamin, Jr., John Hale, Edwin L. Carstensen, and Howard E. Tompkins. Presentation of the paper is presently being scheduled.

Awards

COMMITTEE ON AWARD OF INSTITUTE PRIZES

The award of technical paper prizes was made on a Division basis for the first time during the current administrative year. The committee thinks the selection of the prize papers for the Divisions and also for the student prize paper contest can be handled most effectively by one committee, the Committee on Award of Institute Prizes, which should be composed of working groups in the several fields of interest, corresponding to the Divisions. This method of operation will assure that the prizes will continue to be Institute prizes and that the responsibility for selection will be definitely placed and recognized.

CHARLES LEGEYT FORTESCUE FELLOWSHIP COMMITTEE

The committee held one meeting, in New York, at which time business affairs were discussed and selection of recipients for the academic year 1950–51 was accomplished. Two fellowships, each carrying a stipend of $1,000, were granted. One recipient was Robert R. Johnson, of the University of Wisconsin, who will undertake graduate study in electrical engineering at Yale University. The other winner was Robert E. Horn, of Washington University in St. Louis, who will enter the graduate school of that university for study in electrical engineering. Both of these men had undergraduate records that approached perfection, and are well-balanced personalities as well.

The committee wishes to report a very encouraging response to the fellowship competition last winter. A record number of applications, 23, were received, and nearly all were from well-qualified young men. The committee believes that the fellowship continues to be a very worth-while project.

JOHN FRITZ MEDAL

The John Fritz Medal may be awarded annually for notable scientific or industrial achievements, by a board of award composed of representatives of the American Society of Civil Engineers, The American Society of Mechanical Engineers, American Institute of Mining and Metallurgical Engineers, and AIEE. The 1950 medal was awarded to Walter Hull Aldridge, President of the Texas Gulf Sulphur Company, with the following citation: "As Engineer of mines and statesman of industry who, by his rare technical and administrative skills, has importantly augmented the mineral production of our country and Canada, and who, by giving unselfishly of his wisdom and vision, has guided his professional colleagues to higher achievements."

The medal was presented to him on November 16, 1949, at a dinner at the University Club.

MARSTON MEDAL

The Marston Gold Medal is awarded to an alumnus of Iowa State College, of at least 30 years' standing, for achievement in engineering in a broad field. The board of award includes representatives of the college, and five engineering societies: ASCE, AIME, ASME, AIEE, and American Institute of Chemical Engineers.

WASHINGTON AWARD

The Washington Award for 1950 was made to Wilfred Sykes, President, Inland Steel Company, Chicago, Ill., and was presented at a dinner meeting on February 27. The award is made annually to an outstanding engineer, a citizen or resident of the United States, who ably has served human needs, and is administered by a commission representing the Western Society of Engineers, ASCE, AIME, ASME, and AIEE.

EDISON MEDAL

The Edison Medal for 1949 was awarded to Dr. K. B. McEachron, Manager of Engineering, Transformer and Allied Products Division, General Electric Company, Pittsfield, Mass., "for his contributions to the advancement of electrical science in the field of lightning and other high-voltage phenomena and for the application of this knowledge to the design and production of electric apparatus and systems," and was presented to him on February 1, 1950, in an evening session of the Winter General Meeting.

The medal may be awarded annually for meritorious achievement in electrical science, electrical engineering, or the electrical arts. Awards are made by a committee of 24 members of the Institute.

LAMME MEDAL

The Lamme Medal for 1949 was awarded to C. M. Laffoon, Manager of A-C Engineering Department, Westinghouse Electric Corporation, East Pittsburgh, Pa., "for outstanding contributions to the design of electrical machines, particularly large turbine generators and high-frequency generators." The medal will be presented to him on June 12, 1950, during the Summer and Pacific General Meeting.

The medal may be awarded annually by a committee of nine members to a member of the AIEE for "meritorious achievement in the development of electrical apparatus or machinery."

ALFRED NOBLE PRIZE

The Alfred Noble Prize award is made to a member of any grade of the ASCE, AIME, ASME, AIEE, or WSE for a technical paper of exceptional merit officially accepted for publication in any of their technical publications, provided the author has not passed his 31st birthday at the time the paper is submitted to the society in practically its final form. The prize award carries a handsome certificate and $350 cash. It is an important award, and greater publicity should be given to it by each of the participating societies in order that it will more fully stimulate the writing of papers by young members.

Ten AIEE papers were eligible, and from this group the paper "Relative Surface Voltage Gradients of Grouped Conductors" by M. Temoshok, Associate AIEE, was chosen as most worthy of the award.

After due consideration by the committee, the award was given to J. C. Fisher, ASME, for the paper "Anisotropic Plastic Flow."

It is interesting to note that Mr. Fisher is Research Associate, General Electric Research Laboratory, and that his paper is of the research type with related papers having been previously published in the *Journal of Applied Physics*. The AIEE paper "Relative Surface Voltage Gradients of Grouped Conductors" by Mr. Temoshok was of a different type, being a practical engineering type of paper of great value to the important development of long-distance power transmission at higher voltages than are in current use. It is very difficult when the committee is called upon to judge an engineering paper in comparison with a fundamental research paper.

The Alfred Noble Prize has been awarded each year since 1931, with the exception of 1934, 1935, and 1940, for a total of 16 times. It has been awarded to authors of AIEE papers eight times. However, there has been no award for an AIEE paper for the last five years.

HOOVER MEDAL

In September the Board of Award for the Hoover Medal awarded this distinguished honor to Dr. Frank B. Jewett, past-President of the AIEE. The Hoover Medal is awarded by a board representing the ASCE, AIME, ASME, and AIEE "for outstanding civic or humanitarian activities constituting distinguished public service." The citation accompanying this award is as follows:

FRANK B. JEWETT

> Great pioneer of industrial research, leader in molding scientific and engineering work to the needs of humanity, distinguished organizer of scientific effort for the service of the nation in war and peace.

The Institute suffered a great loss in the death of Dr. Jewett in November last. Accordingly, the medal was presented posthumously with appropriate ceremonies on Wednesday evening, February 1, during the Winter General Meeting of the Institute. Dr. Gano Dunn presented a statement of the achievements of the Medalist. The medal was presented by Dr. Scott Turner, Chairman of the Hoover Medal Board of Award, and it was received on behalf of his father by Harrison L. Jewett, Dr. Jewett's elder son, and himself a member of the Institute.

Joint Activities

UNITED ENGINEERING TRUSTEES, INC.

The funds and property held jointly by the four Founder Societies, including the Engineering Societies Building, the Engineering Societies Library, and the endowment funds of the Engineering Foundation, are administered by the United Engineering

Trustees, Inc., which also serves as treasurer of the Engineers' Council for Professional Development.

The building is fully occupied, and two of the Founder Societies have substantial amounts of space in other buildings.

The corporation is making studies of the possibility of securing a more modern building for the engineering societies.

ENGINEERING FOUNDATION

The Engineering Foundation is a department of the United Engineering Trustees, Inc., and its general objective is "the furtherance of research in science and engineering."

With the income from its endowment funds, it supports a broad range of research projects, now numbering about 15. Some of its most effective contributions are those supporting studies and analyses necessary in the early stages of organizing projects on such bases that financial support from other sources becomes available. A special study is being devoted to the future employment of foundation funds in advancing research.

ENGINEERING SOCIETIES LIBRARY

The library is a department of the United Engineering Trustees, Inc., and was formed by combining the separate libraries of the ACSE, AIME, ASME, and AIEE, and is conducted as a free public reference library.

In addition to affording the use of a large collection of engineering books and periodicals, the library renders special services such as bibliographies, translations, photostats, searches, and book loans by mail.

A broad survey has been made for the purpose of reorienting the library with other technical libraries in the United States and for improving its services.

Many valuable gifts of books and periodicals were received during the past year.

ENGINEERS' COUNCIL FOR PROFESSIONAL DEVELOPMENT

The principal activities of ECPD include programs for the guidance of young persons thinking of entering the engineering field, the accrediting of curricula of engineering schools, and encouragement and assistance to individuals in their engineering and cultural studies during several years following graduation. The council represents ASCE, AIME, ASME, AIEE, AIChE, the Engineering Institute of Canada, the American Society for Engineering Education, and the National Council of State Boards of Engineering Examiners.

ECPD approved and referred to the constituent societies the report of the Committee on Professional Recognition recommending the adoption of uniform grades of membership. The AIEE Board of Directors has approved the uniform grades for submission to the membership by letter ballot after they are approved by at least two other societies.

THE NATIONAL FIRE WASTE COUNCIL

A meeting of the National Fire Waste Council was held in Washington, D. C., Friday, March 31. The meeting was well attended, 55 of the 58 members having been present.

It was pointed out that the fire loss in 1949 amounted to 700 million dollars. This is equivalent to a $5 per capita loss. The association is attempting to reduce this loss which is enormous, particularly when it is compared with the figures for Britain, where the loss is 50 cents per capita, and with Germany, where it is 12 cents per capita. The majority of fires are due to carelessness; matches and smoking are responsible for the largest number. The next most common cause is defective wiring. The AIEE and its affiliates might well consider means of reducing this. The council is extremely anxious to reduce the fire loss, and it was pointed out by the speakers that the first step in any locality is the adoption of a fire prevention code; the second, the enforcement of this code. The National Board of Fire Underwriters has available a sample code. The council works through the Chambers of Commerce in the various localities and through these local Chambers attempts to educate the citizens and school children in fire protection. The council's plan is to organize in each Chamber a fire prevention committee to handle the problem in the locality.

In addition, the council is carrying on a hospital inspection program. This inspection is made available to hospitals, but no legal pressure is brought to bear. The committee reported that the larger hospitals welcome the inspection. They also stated that it was only the small hospitals that do not wish to be inspected. It was thought that the communities should be informed of the program; that they should assume the responsibility of seeing that it is carried out.

The Red Cross pointed out that there were 317 disasters (a disaster occurs when five or more families are involved) in 1949, of which 170 were caused by fires. It was stated that well over half of the disasters in this country are due to fires. The Red Cross is active in providing literature on fire prevention.

REPRESENTATIVES

A complete list of about 40 joint bodies upon which the Institute is represented appears in the Year Book and in the October issue of *Electrical Engineering* each year.

Appreciation

The Board of Directors notes with much satisfaction the continuing rapid increase in the membership and the substantial expansion in the activities of the general and technical committees, and the District, Section, and Branch officers and committees.

The Board of Directors expresses its deepest appreciation of the splendid co-operation received from all of these groups and from the membership in general.

Respectfully submitted for the Board of Directors.

H. H. HENLINE
Secretary

HASKINS & SELLS
CERTIFIED PUBLIC ACCOUNTANTS

250 PARK AVENUE
NEW YORK 17

ACCOUNTANTS' CERTIFICATE

American Institute of Electrical Engineers:

We have examined the balance sheet of American Institute of Electrical Engineers, and schedule of securities owned, as of April 30, 1950, and the related statements of income and operating fund reserve and of restricted fund reserves for the year then ended. Our examination was made in accordance with generally accepted auditing standards, and accordingly included such tests of the accounting records and such other auditing procedures as we considered necessary in the circumstances.

In our opinion, the accompanying balance sheet, schedule of securities owned, and statements of income and operating fund reserve and of restricted fund reserves, respectively, present fairly the financial position of, and securities owned by, the Institute at April 30, 1950, and the results of its operations for the year then ended, in conformity with generally accepted accounting principles applied on a basis consistent with that of the preceding year.

(*Signed*) HASKINS & SELLS

New York,
May 17, 1950

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Balance Sheet, April 30, 1950

Exhibit A

ASSETS

Property Fund Assets:		
One-fourth interest in physical properties of United Engineering Trustees, Inc.:		
Land, buildings, and equipment (less depreciation and renewal reserve)	$320,525.41	
Funded depreciation and renewal reserve	177,923.07	
Total	$498,448.48	
Equipment:		
Library (volumes and fixtures)—estimated value	36,366.37	
Office furniture and fixtures (less reserve for depreciation, $33,849.74)	26,070.65	
Works of art, etc.	3,001.35	
Total property fund assets		$ 563,886.85
Restricted Fund Assets:		
Securities—at cost (quoted market value, $633,201.43)—Schedule 1	$572,455.35	
Cash (including $12,626.78 Canadian funds):		
Reserve capital fund	9,266.71	
Life Membership fund	2,409.81	
Member-for-Life fund	6,236.86	
International Electrical Congress of St. Louis Library fund	873.69	
Lamme Medal fund	160.00	
Mailloux fund	1,021.38	
Volta Memorial fund	401.48	
Retired employees insurance fund	2,000.00	
Accrued interest receivable	319.98	
Total restricted fund assets		595,145.26
Operating Fund Assets:		
Cash (not including $1,655.69 for Federal taxes withheld from employees)	$ 12,977.22	
Accounts receivable:		
Members—for dues (less reserve, $6,300.00)	12,849.68	
Advertisers	2,218.70	
Miscellaneous	4,388.71	
Technical Conference loans	650.00	
Accrued interest receivable	2,360.83	
Inventories:		
Transactions, etc.	1,764.00	
Text and cover paper	15,511.21	
Badges	12,336.24	
Deferred charges—Production charges for May issue of *Electrical Engineering*	16,089.81	
Total operating fund assets		81,146.40
Total		$1,240,178.51

LIABILITIES

Property Fund Reserve		$ 563,886.85
Restricted Fund Reserves (Exhibit *C*):		
Reserve capital fund	$543,295.65	
Life Membership fund	7,610.88	
Member-for-Life fund	11,288.94	
International Electrical Congress of St. Louis Library fund	6,382.33	
Lamme Medal fund	4,440.44	
Mailloux fund	1,021.38	
Volta Memorial fund	19,105.64	
Retired employees insurance fund	2,000.00	
Tota restricted fund reserves		595,145.26
Operating Fund Reserves, Liabilities, etc.:		
Accounts payable	$ 40,122.69	
Deferred income:		
Dues received in advance	4,155.75	
Entrance fees and dues advanced by applicants for membership	1,815.75	
Subscriptions to publications received in advance	21,501.00	
Miscellaneous (including unallocated receipts)	1,493.48	
Operating fund reserve (Exhibit *B*)	12,057.73	
Total operating fund reserves, liabilities, etc.		81,146.40
Total		$1,240,178.51

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Exhibit B — **Statement of Income and Operating Fund Reserve for the Year Ended April 30, 1950**

Income:

Officers of A.I.E.E. for 1950–1951

PRESIDENT

TITUS G. LECLAIR
Chicago, Ill.
(Term expires July 31, 1951)

PAST PRESIDENTS

EVERETT S. LEE, Schenectady, N. Y.
(Term expires July 31, 1951)

JAMES F. FAIRMAN, New York, N. Y.
(Term expires July 31, 1952)

VICE-PRESIDENTS

District
2 C. G. VEINOTT, Lima, Ohio
4 Walter J. SEELEY, Durham, N. C.
6 W. C. DUVALL, Boulder, Colo.
8 RALPH A. HOPKINS, Los Angeles, Calif.
10 A. H. FRAMPTON, St. Catharines, Ont.
(Terms expire July 31, 1951)

District
1 J. G. TARBOUX, Ithaca, N. Y.
3 C. S. PURNELL, New York, N. Y.
5 J. R. NORTH, Jackson, Mich.
7 H. R. FRITZ, St. Louis, Mo.
9 J. A. McDONALD, Salt Lake City, Utah
(Terms expire July 31, 1952)

DIRECTORS

W. L. EVERITT, Urbana, Ill.
A. C. MONTEITH, Pittsburgh, Pa.
ELGIN B. ROBERTSON, Dallas, Tex.
(Terms expire July 31, 1951)

C. W. FICK, Cleveland, Ohio
M. D. HOOVEN, Newark, N. J.
F. O. McMILLAN, Corvallis, Oreg.
(Terms expire July 31, 1952)

Ernest W. DAVIS, Cambridge, Mass.
N. B. HINSON, Los Angeles, Calif.
H. J. SCHOLZ, Birmingham, Ala.
(Terms expire July 31, 1953)

Walter J. BARRETT, Newark, N. J.
Allen G. DEWARS, Minneapolis, Minn.
VICTOR SIEGFRIED, Worcester, Mass.
(Terms expire July 31, 1954)

TREASURER

W. I. SLICHTER, New York, N. Y.
(Term expires July 31, 1951)

SECRETARY

H. H. HENLINE, New York, N. Y.
(Term expires July 31, 1951)

LOCAL HONORARY SECRETARIES

AUSTRALIA—V. J. F. Brain, Electricity Authority of N.S.W., Box 2600 G.P.O., Sydney, New South Wales

Honorary Members, 1884–1950

*Sir William Preece.....1884
*Norvin Green.....1889
*Moses G. Farmer.....1890
*Lord Kelvin.....1892
*Cyrus Field.....1892
*E. W. von Siemens.....1892
*Andre E. Blondel.....1912
*C. E. L. Brown.....1912
*Emil A. Budde.....1912
*S. Z. de Ferranti.....1912
*Antonio Pacinotti.....1912
*S. P. Thompson.....1914
*Guglielmo Marconi.....1917
*Oliver Heaviside.....1918
*Ferdinand Foch.....1921
*Thomas A. Edison.....1928
*John J. Carty.....1928
*M. I. Pupin.....1928
*Ambrose Swasey.....1928
*Elihu Thomson.....1928
Herbert Hoover.....1929
*Charles F. Scott.....1929
*Charles F. Brush.....1929
Motoji Shibusawa.....1929
*Frank J. Sprague.....1932
*W. L. R. Emmet.....1933
*G. A. Hamilton.....1933
*Arthur E. Kennelly.....1933
R. A. Millikan.....1933
*E. W. Rice, Jr.....1933
*Edward Weston.....1933
*Bion J. Arnold.....1937
*Alex Dow.....1937
*Cummings C. Chesney.....1938
Andrew G. L. McNaughton.....1942
Dugald C. Jackson.....1944
*Charles E. Skinner.....1945
Gano Dunn.....1945
*Frank B. Jewett.....1945
Vannevar Bush.....1949

* Deceased.

See page 120 for information concerning living Honorary Members.

Headquarters Staff

33 West 39th Street, New York 18

Secretary.....H. H. Henline

Western Virginia	4	June 23, '49	B. H. Adkins	H. E. Rothwell	2307 Dennston Ave., Roanoke 15, Va.
Wichita	7	Sept. 16, '37	Charles Yoe	O. R. Hantla	Kansas Gas & Electric Co., Box 208, Wichita, Kans.
Worcester	1	Feb. 18, '20	R. E. Pfeif	W. G. Coleman	General Electric Co., 507 Main St., Worcester 8, Mass.
Total Sections	88				

Subsections

Name	Chairman	Secretary	Secretary's Address
Albuquerque (New Mexico-West Texas Section)	L. C. Trunler	A. D. Taylor	3306—43rd Place, Sandia Base, Albuquerque, N. Mex.
Baton Rouge (New Orleans Section)	L. V. McLean	W. S. Syrett	1366 Stephens Ave., Baton Rouge 15, La.
Billings (Montana Section)	H. A. Black	L. R. Stickelberger	502 5th Ave., Laurel, Mont.
Binghamton Area (Ithaca Section)	W. J. Rider	L. F. McGowan	North Chenango St., Greene, N. Y.
Black Hills (Denver Section)	J. O. Kammerman	Robert G. Aehrim	Black Hills Power and Light Co., Rapid City, S. D.
Boulder City (Los Angeles Section)	W. M. Doak	L. J. Hudlow	U. S. Bureau of Reclamation, 315 Utah St., Boulder City, Nev.
Casper, Wyo. (Denver Section)	A. Braitman	E. Krupotich	740 South Grant St., Casper, Wyo.
Central Texas (North Texas Section)	J. R. Moore, Jr.	Earl Hinson, Jr.	3024 Wenz Ave., Waco, Tex.
Centre County (Pittsburgh Section)	H. I. Tarpley	J. A. Wensel	Ordnance Research Lab., Box 30, State College, Pa.
Charleston (South Carolina Section)	C. T. Razor	T. C. R. Legare	103 Pine St., Ashley Forest, Charleston, S. C.
Charlotte (North Carolina Section)	I. G. Wallace, Jr.	W. C. Burnett	Box 240, Charlotte 1, N. C.
Columbia (South Carolina Section)	Orem Long	J. T. Steppe, Jr.	3950 Live Oak St., Columbia, S. C.
Corpus Christi (South Texas Section)	M. D. Jester	J. E. Dean	Texas College of Arts & Industries, Kingsville, Tex.
Eastern Shore (Maryland Section)	C. D. Appleby	C. M. Mullican, Jr.	Salisbury C & P Telephone Co. of D. C., 208 East Church St., Salisbury, Md.
Eureka (San Francisco Section)	A. E. Gleisberg	M. D. McLellan	Pacific Tel. & Tel. Co., Eureka, Calif.
Fort Worth (North Texas Section)	C. K. Beyette	Harold Farrington	Texas Electric Service Co., P. O. Box 970, Fort Worth 1, Tex.
Fox River Valley (Milwaukee Section)	J. J. Rock	W. W. Lund	Kurz & Root Co., Appleton, Wis.
Freeport (Houston Section)	W. D. Coar	R. T. Windecker	P. O. Box 33, Lake Jackson, Tex.
Fresno Division (San Francisco Section)	W. M. Green	G. W. Hayden	4325 Iowa Ave., Fresno 2, Calif.
Great Falls (Montana Section)	W. Lowe	J. Radcliffe	2805 First Ave., N., Great Falls, Mont.
Hamilton (Toronto Section)	J. P. Skillen	C. V. Ryder	396 Main St. E., Hamilton, Ont., Canada
Hampton Roads (Virginia Section)	S. H. Fletcher	L. E. Rhinesmith	1119 East Warwick Road, R. D. 1, Box 35, Hilton Village, Va.
Hudson Valley Division (New York Section)	M. F. Clement	A. V. Platter	International Business Machines, Poughkeepsie, N. Y.
Jackson (Miss.) (New Orleans Section)	A. N. Saxon	W. L. Harp	Southern Bell Tel. & Tel. Co., P. O. Box 811, Jackson 106, Miss.
Jacksonville (Florida Section)			
Johnstown (Pittsburgh Section)	B. H. Drum	R. S. Baum	University of Pittsburgh, 325 Cypress Ave., Johnstown, Pa.
Lake Charles (New Orleans Section)	J. J. Alleman	C. Valdes	738 Kirkby St., Lake Charles, La.
Lancaster-York (Maryland Section)	F. C. Sieber	G. E. Cons, Jr.	Allis-Chalmers Mfg. Co., 42 East King St., York, Pa.
Lima (Dayton Section)	O. M. Swain	E. S. Reed	Westinghouse Electric Corp., Lima, Ohio
Mid-State (North Carolina Section)	H. G. Taylor	S. M. Sprowl, Jr.	P. O. Drawer K-1, Greensboro, N. C.
Mobile-Pensacola (Alabama Section)	R. L. Pulley	A. M. Quarterman	Yonge & Hart, 611 Blount Bldg., Pensacola, Fla.
Muscle Shoals (East Tennessee Section)			
Nashville (Memphis Section)	J. L. Simpson, Jr.	W. Criley	Vanderbilt Univ., Nashville 4, Tenn.
New Hampshire (Boston Section)	W. C. Tallman	P. W. Buxton	Public Service Co. of N. H., 205 Main St., Nashua, N. H.
New Jersey Division (New York Section)	F. Seely	E. H. Shimp	Pub. Serv. Elec. & Gas Co., 938 Clinton Ave., Irvington 11, N. J.
Northwest Arkansas (Arkansas Section)	V. V. Fletcher	F. M. Hinkle	411 Rebecca St., Fayetteville, Ark.
Quad-Cities (Iowa Section)	M. P. Roller	A. W. Kremer	Allis-Chalmers Mfg. Co., 901 Kahl Bldg., Davenport, Iowa
Red River Valley Division (Minnesota Section)	B. H. Barnard	R. Faiman	North Dakota Agri. College, Fargo, N. Dak.
Richmond (Virginia Section)	L. D. Johnson, III	C. E. McMurdo	3523 Patrick Ave., Richmond 22, Va.
Ridgway (Erie Section)	R. F. Edwards	J. H. Schneider	217 Little Ave., Ridgway, Pa.
St. Lawrence International (Syracuse Section)	P. F. Mengel	L. F. Pries	New York State Agric. & Tech. Inst., 8 College St., Canton, N. Y.
St. Maurice Valley (Montreal Section)	D. King	G. Auger	Aluminum Co. of Canada, Shawinigan Falls, P. Q., Canada
San Jose (San Francisco Section)	W. Raab	A. F. Lowe	Pacific Tel. & Tel. Co., 1199 Lennon Way, San Jose, Calif.
Sangamon (Illinois Valley Section)	C. P. Hafel	F. C. Blythe	P. O. Box 37, Springfield, Ill.
Savannah (Georgia Section)	E. H. Overby	E. B. Dawson	Savannah Armature Works, Inc., 126 West Bay St., Savannah, Ga.
Shasta Division (San Francisco Section)	Roy Greer	A. A. Craig	220 West St., Willows, Calif.
Tacoma (Seattle Section)	H. M. Manning	H. A. Brenner	General Electric Co., P. O. Box 1485, Tacoma 1, Wash.
Tri-State Division (West Virginia Section)			
Vancouver Island (Vancouver Section)	A. Bradfield	J. B. Hedley	The B. C. Power Commission, Victoria, B. C., Canada
West Central Texas Division (North Texas Section)	C. V. Herbert	J. G. McKeown	880 Ross Ave., Abilene, Tex.
West Coast (Florida Section)			
West Michigan (Michigan Section)	P. R. Coffman	L. A. Zaborsky	127 Colfax, N. E., Grand Rapids, Mich.
Wilmington (Philadelphia Section)	W. J. Mearns	M. G. Young	Univ. of Delaware, Newark, Del.
Zanesville (Columbus Section)	A. Wurdack	F. Nikel	743 Convers Ave., Zanesville, Ohio

Geographical District Executive Committees

District	Chairman (Vice-President, AIEE)	Secretary (District Secretary)	Chairman, District Committee on Student Activities
1 North Eastern	J. G. Tarboux, Cornell University, Ithaca, N. Y.	E. B. Alexander, New York State Elec. & Gas Corp., 62 Henry St., Binghamton, N. Y.	H. F. Cooke, University of Syracuse, Syracuse 10, N. Y.
2 Middle Eastern	C. G. Veinott, Westinghouse Electric Corp., Lima, Ohio	W. A. Dynes, 312 Lonsdale Ave., Dayton 9, Ohio	J. S. Antel, Jr., George Washington University, Washington 7, D. C.
3 New York City	C. S. Purnell, Westinghouse Electric Corp., 40 Wall St., New York 5, N. Y.	D. W. Taylor, Public Service Elec. & Gas Co., 80 Park Place, Newark 1, N. J.	R. T. Weil, Manhattan College, New York 63, N. Y.
4 Southern	W. J. Seeley, Duke University, Durham, N. C.	Russell Ranson, 116½ East Fourth St., Charlotte 2, N. C.	P. H. Nelson, University of Florida, Gainesville, Fla.
5 Great Lakes	J. R. North, Commonwealth Services, Inc., 212 W. Michigan Ave., Jackson, Mich.	G. M. Chute, General Electric Co., 700 Antoinette St., Detroit 2, Mich.	H. S. Dixon, North Dakota Agri. College, State College Sta., Fargo, N. Dak.
6 North Central	W. C. DuVall, University of Colorado, Boulder, Colo.	G. E. Gless, Jr., University of Colorado, Boulder, Colo.	E. J. Ballard, Jr., University of Nebraska, Lincoln 8, Nebr.
7 South West	H. R. Fritz, Southwestern Bell Tel. Co., 2502 Telephone Bldg., St. Louis 1, Mo.	R. C. Meyerand, Union Elec. Co. of Missouri, 315 No. 12th Blvd., St. Louis 1, Mo.	A. J. McCrocklin, Jr., University of Texas, Engg. Bldg. 145, Austin 18, Tex.
8 Pacific	R. A. Hopkins, Westinghouse Electric Corp., 600 St. Paul Ave., Los Angeles 14, Calif.	T. M. Blakeslee, Dept. of Water & Power, Box 3669 Terminal Annex, Los Angeles 54, Calif.	R. M. Saunders, University of Calif., Berkeley 4, Calif.
9 North West	J. A. McDonald, General Electric Co., 200 So. Main St., Salt Lake City, Utah	F. O. Wald, Utah Power & Light Co., P. O. Box 899, Salt Lake City 10, Utah	O. C. Haycock, University of Utah, Salt Lake City Utah
10 Canada	A. H. Frampton, English Elec. Co. of Canada, Ltd., St. Catharines, Ont., Canada	John I. Gram, Hydro-Electric Power Comm. of Ont., Box 237, Niagara Falls, Ont., Canada	

NOTE: Each District Executive Committee includes also the Chairmen and Secretaries of all Sections within the District, the District Vice-Chairman of the AIEE Membership Committee, and a member of the Sections Committee who is resident in the District.

Committees and Representatives for 1950–51

General Committees

Executive

Titus G. LeClair, *Chairman;* Commonwealth Edison Company, 72 West Adams St., Chicago 90, Ill.
W. J. Barrett — Newark, N. J.
W. L. Everitt — Urbana, Ill.
J. F. Fairman — New York, N. Y.
Everett S. Lee — Schenectady, N. Y.
A. C. Monteith — Pittsburgh, Pa.
W. I. Slichter — New York, N. Y.

Board of Examiners

P. H. Adams, *Chairman;* Public Service Electric and Gas Company, 80 Park Place, Newark 1, N. J.
Sidney Withington *Vice-Chairman* — New Haven, Conn.
John J. Anderson, Jr., *Secretary* — AIEE Headquarters
A. E. Anderson — Philadelphia, Pa.
R. W. Atkinson — Bayonne, N. J.
R. H. Barclay — New York, N. Y.
C. R. Beardsley — New York, N. Y.
C. A. Butcher — Ampere, N. J.
J. L. Callahan — New York, N. Y.
H. A. Dambly — Philadelphia, Pa.
E. W. Davis — Cambridge, Mass.
G. W. Douglass — Newark, N. J.
E. D. Doyle — Philadelphia, Pa.
C. W. Franklin — New York, N. Y.
W. N. Goodwin, Jr. — Newark, N. J.
S. B. Grisdom — East Pittsburgh, Pa.
N. S. Hibshman — Brooklyn, N. Y.
L. F. Hickernell — Hastings-on-Hudson, N. Y.
J. W. Horton — New London, Conn.
A. E. Knowlton — Short Beach, Conn.
Henry Logan — New York, N. Y.
Lee M. Moore — Columbus, Ohio
L. G. Pacini — New York, N. Y.
F. O. Runyon — Newark, N. J.
F. J. Scudder — Manhasset, N. Y.
B. E. Shackelford — New York, N. Y.
H. W. Tenney — Jersey City, N. J.
Gordon Thompson — New York, N. Y.
Robert Treat — Schenectady, N. Y.
H. M. Trueblood — Dobbs Ferry, N. Y.
B. Van Ness, Jr. — Baltimore, Md.
R. G. Warner — New Haven, Conn.
S. S. Watkins — New York, N. Y.
Roland Whitehurst — Philadelphia, Pa.

Constitution and Bylaws

N. B. Hinson, *Chairman;* Southern California Edison Company, Ltd., Edison Building, Los Angeles 53, Calif.
F. M. Farmer — New York, N. Y.
W. Scott Hill — Pittsfield, Mass.
B. D. Hull — Dallas, Tex.
W. W. Lewis — Schenectady, N. Y.
W. S. Peterson — Los Angeles, Calif.
Walter C. Smith — Palo Alto, Calif.
E. P. Yerkes — Philadelphia, Pa.

Finance

W. J. Barrett, *Chairman;* New Jersey Bell Telephone Company, Engineering Department, Room 1405, 540 Broad Street, Newark 2, N. J.
M. D. Hooven — Newark, N. J.
C. S. Purnell — New York, N. Y.

Headquarters

D. W. Taylor, *Chairman;* Public Service Electric and Gas Company, 80 Park Place, Newark 1, N. J.
W. J. Barrett — Newark, N. J.
H. H. Henline — New York, N. Y.

Members-for-Life Fund

N. E. Funk, *Chairman;* 1520 Spruce Street, Philadelphia 2, Pa.
T. F. Barton — New York, N. Y.
C. R. Beardsley — New York, N. Y.
Mark Eldredge — Washington, D. C.
A. H. Hull — Toronto, Ontario, Canada
B. D. Hull — Dallas, Tex.

(Continued in next column)

E. H. Martindale — Cleveland, Ohio
W. I. Slichter — New York, N. Y.
R. W. Sorensen — Pasadena, Calif.
J. F. Tritle — Erie, Pa.
E. P. Yerkes — Philadelphia, Pa.

Membership

J. C. Woods, *Chairman;* Commonwealth Edison Company, 72 West Adams Street, Chicago 90, Ill.
Charles Clos, *Vice-Chairman* — New York, N. Y.
F. A. Norris, *Secretary* — AIEE Headquarters
E. W. Allen — Oklahoma City, Okla.
F. S. Black — New York, N. Y.
W. C. Bloomquist — Schenectady, N. Y.
C. W. Fick — Cleveland, Ohio
Thomas Ingledow — Vancouver, British Columbia, Canada
C. R. Kingsbury — Seattle, Wash.
W. S. Leake — New Orleans, La.
E. W. Morris — Los Angeles, Calif.
C. G. Rumohr — Denver, Colo.
P. L. Savage — Los Angeles, Calif.
W. E. Scholz — Philadelphia, Pa.

District Vice-Chairman

1 T. M. Linville — Schenectady, N. Y.
2 M. L. Lehman — Philadelphia, Pa.
3 M. A. Jones — Newark, N. J.
4 J. D. Harper — Alcoa, Tenn.
5 H. R. Heckendorn — Chicago, Ill.
6 J. L. McKinley — Denver, Colo.
7 R. G. Kloeffler — Manhattan, Kans.
8 B. L. Robertson — Berkeley, Calif.
9 H. B. Hodgins — Salt Lake City, Utah
10 C. L. Roach — Montreal, Quebec, Canada

Planning and Co-ordination

M. D. Hooven, *Chairman;* Public Service Electric and Gas Company, 80 Park Place, Newark 1, N. J.
W. J. Barrett — Newark, N. J.
J. L. Callahan — New York, N. Y.
F. E. Harrell — Cleveland, Ohio
H. H. Henline — New York, N. Y.
W. Scott Hill — Pittsfield, Mass.
A. E. Knowlton — Short Beach, Conn.
Elgin B. Robertson — Dallas, Tex.
M. J. Steinberg — New York, N. Y.
C. H. Willis — Princeton, N. J.

Publication

K. B. McEachron, *Chairman;* General Electric Company, 100 Woodlawn Avenue, Pittsfield, Mass.
F. R. Benedict — East Pittsburgh, Pa.
P. B. Garrett — Chicago, Ill.
R. K. Honaman — New York, N. Y.
F. O. McMillan — Corvallis, Oreg.
T. A. O'Halloran — Washington, D. C.
G. C. Quinn — Milwaukee, Wis.
C. S. Rich — New York, N. Y.
G. C. Tenney — San Francisco, Calif.
C. H. Willis — Princeton, N. J.

Public Relations

G. T. Minasian, *Chairman;* Consolidated Edison Company of New York, Inc., 4 Irving Place, New York 3, N. Y.
Guy Bartlett — Schenectady, N. Y.
G. W. Bower — Haddonfield, N. J.
V. A. Diggs — Cleveland, Ohio
R. T. Ferris — Philadelphia, Pa.
H. H. Henline — New York, N. Y.
R. K. Honaman — New York, N. Y.
J. T. Kimball — Phoenix, Ariz.
A. E. Knowlton — Short Beach, Conn.
G. J. Lowell — New York, N. Y.
H. W. Marquardt — New York, N. Y.
K. B. McEachron — Pittsfield, Mass.
J. P. Neubauer — New York, N. Y.
H. J. Schols — Birmingham, Ala.
W. B. Stephenson — Oklahoma City, Okla.
O. W. Titus — Toronto, Ontario, Canada
C. H. Willis — Princeton, N. J.

Research

M. J. Kelly, *Chairman;* Bell Telephone Laboratories, Inc., 463 West Street, New York 14, N. Y.
J. A. Hutcheson, *Vice-Chairman* — East Pittsburgh, Pa.
M. B. Long, *Secretary* — New York, N. Y.
B. G. Ballard — Ottawa, Ontario, Canada
J. W. Barker — New York, N. Y.
R. D. Bennett — Silver Spring, Md.
L. V. Berkner — Washington, D. C.
E. W. Boehne — Cambridge, Mass.
Cledo Brunetti — Stanford, Calif.
C. R. Burrows — Ithaca, N. Y.
A. G. Conrad — New Haven, Conn.
H. P. Corwith — New York, N. Y.
H. E. Edgerton — Cambridge, Mass.
M. A. Edwards — Schenectady, N. Y.
W. L. Everitt — Urbana, Ill.
R. S. Glasgow — Annapolis, Md.
T. J. Killian — Washington, D. C.
J. T. Littleton — Corning, N. Y.
A. D. Moore — Ann Arbor, Mich.
B. K. Northrop — Ithaca, N. Y.
W. H. Pickering — Pasadena, Calif.
C. S. Schifreen — Philadelphia, Pa.
E. F. Seaman — Washington, D. C.
C. G. Suits — Schenectady, N. Y.
J. B. Thomas — Fort Worth, Tex.
E. A. Walker — Arlington, Va.
V. K. Zworykin — Princeton, N. J.

Safety

W. B. Kouwenhoven, *Chairman;* The Johns Hopkins University, Baltimore 18, Md.
M. M. Brandon, *Vice-Chairman and Secretary,* — New York, N. Y.
Robin Beach — Brooklyn, N. Y.
J. H. Berry — Norfolk, Va.
Handley Blackmon — Pittsburgh, Pa.
W. B. Buchanan — Toronto, Ontario, Canada
C. F. Dalziel — Berkeley, Calif.
G. S. Diehl — Lancaster, Pa.
W. P. Dobson — Toronto, Ontario, Canada
J. P. Ferguson — Brooklyn, N. Y.
J. M. Flanigen — Atlanta, Ga.
C. E. Ganther — Cleveland, Ohio
J. A. Gienger — Rochester, N. Y.
M. C. Goodspeed — Harborcreek, Pa.
Floyd Goss — Los Angeles, Calif.
N. B. Hinson — Los Angeles, Calif.
O. S. Hockaday — Fort Worth, Tex.
J. O. Leslie — Reading, Pa.
R. L. Lloyd — Washington, D. C.
Albrecht Naeter — Stillwater, Okla.
G. R. Radley — Milwaukee, Wis.
P. X. Rice — State College, Pa.
W. T. Rogers — New York, N. Y.
A. H. Schirmer — New York, N. Y.
J. C. Strasbourger — Cleveland, Ohio
E. E. Turkington — Boston, Mass.
H. H. Watson — Bridgeport, Conn.
H. B. Williams — New York, N. Y.
Wm. R. Wood — Windber, Pa.

Sections

D. I. Anzini, *Chairman;* General Electric Company, 806 Russ Building, San Francisco 6, Calif.
C. S. Purnell, *Vice-Chairman* (East) — New York, N. Y.
Walter C. Smith, *Vice-Chairman* (West) — Palo Alto, Calif.
F. S. Benson, *Secretary* — San Francisco, Calif.
F. S. Black — New York, N. Y.
G. W. Bower — Newark, N. J.
T. C. D. Churchill — Toronto, Ontario, Canada
Bradley Coazens — Los Angeles, Calif.
H. A. Dambly — Philadelphia, Pa.
O. R. Enriquez — Mexico, Federal District, Mexico
C. W. Fick — Cleveland, Ohio
D. E. Garr — Schenectady, N. Y.
R. C. Horn — St. Louis, Mo.
C. W. Keller — Denver, Colo.
R. E. Kistler — Seattle, Wash.
C. P. Knost — New Orleans, La.

(Continued in next column)

A. L. O'Banion — Boston, Mass.
F. H. Pumphrey — Gainesville, Fla.
E. T. Sherwood — Milwaukee, Wis.
D. W. Taylor — Newark, N. J.
H. H. Wagner — Canonsburg, Pa.

Standards

E. B. Paxton, *Chairman;* General Electric Company, 1 River Road, Schenectady 5, N. Y.
C. M. Gilt, *Vice-Chairman* — New York, N. Y.
John J. Anderson, Jr., *Secretary* — AIEE Headquarters
Joseph Wm. Allen — Teterboro, N. J.
R. W. Atkinson — Bayonne, N. J.
R. L. Bailey — Highland Park, Mich.
Sterling Beckwith — Milwaukee, Wis.

J. J. Tesar — Cleveland, Ohio
W. W. Walters — Chicago, Ill.
F. W. Willcutt — Washington, D. C.
H. R. Wood — Boston, Mass.

Professional Division Committees

Professional Division Advisory

W. Scott Hill, *Chairman;* Commercial Engineering Division, General Electric Company, 100 Woodlawn Avenue, Pittsfield, Mass.
F. S. Black, *Vice-Chairman* New York, N. Y.
A. G. Conrad New Haven, Conn.
A. H. Kehoe New York, N. Y.
J. B. MacNeill East Pittsburgh, Pa.
F. O. McMillan Corvallis, Oreg.
A. C. Monteith Pittsburgh, Pa.
H. N. Muller, Jr. East Pittsburgh, Pa.
J. J. Orr New York, N. Y.
Elgin B. Robertson Dallas, Tex.
R. W. Sorensen Pasadena, Calif.

Charles LeGeyt Fortescue Fellowship

J. W. Barker New York, N. Y.
R. I. Wilkinson New York, N. Y.
(Terms expire July 31, 1951)
F. W. Bush Milwaukee, Wis.
A. G. Conrad, *Chairman* New Haven, Conn.
(Terms expire July 31, 1952)
Guy Klein East Pittsburgh, Pa.
F. E. Sanford Jackson, Mich.
(Terms expire July 31, 1953)

Code of Principles of Professional Conduct

R. W. Sorensen, *Chairman;* 384 South Holliston Ave., Pasadena 5, Calif.
Dugald C. Jackson, *Honorary Chairman* Cambridge, Mass.
R. E. Argersinger Boston, Mass.
Harry Barker New York, N. Y.
Edith Clarke Austin, Tex.
F. F. Evenson San Diego, Calif.
E. S. Fields Cincinnati, Ohio
C. A. Heinze Los Angeles, Calif.
W. B. Kouwenhoven Baltimore, Md.
R. D. Maxson Chicago, Ill.
E. L. Moreland Boston, Mass.
J. S. Waters Houston, Tex.

Edison Medal

Appointed by the President for term of five years

C. A. Corney Boston, Mass.
J. R. North Jackson, Mich.
I. M. Stein Philadelphia, Pa.
(Terms expire July 31, 1951)
Marvin W. Smith Philadelphia, Pa.
H. S. Osborne New York, N. Y.
H. A. Winne Schenectady, N. Y.
(Terms expire July 31, 1952)
D. I. Cone San Francisco, Calif.
J. B. MacNeill, *Chairman* East Pittsburgh, Pa.
Philip Sporn New York, N. Y.
(Terms expire July 31, 1953)
J. L. Callahan New York, N. Y.
J. M. Flanigen Atlanta, Ga.
R. I. Wilkinson New York, N. Y.
(Terms expire July 31, 1954)
J. F. Calvert Evanston, Ill.
B. A. Case Swampscott, Mass.
John Grotzinger Akron, Ohio
(Terms expire July 31, 1955)

Members of Board of Directors elected by the Board for term of two years

W. L. Everitt Urbana, Ill.
A. H. Frampton St. Catharines, Ontario, Canada
A. C. Monteith Pittsburgh, Pa.
(Terms expire July 31, 1951)
M. D. Hooven Newark, N. J.
F. O. McMillan Corvallis, Oreg.
C. S. Purnell New York, N. Y.
(Terms expire July 31, 1952)

Education

H. N. Muller, Jr., *Chairman;* Westinghouse Electric Corporation, East Pittsburgh, Pa.
J. D. Ryder, *Vice-Chairman* Urbana, Ill.
M. L. Waring, *Secretary* New York, N. Y.
E. B. Alexander Binghamton, N. Y.
(Continued in next column)
E. D. Ayres Columbus, Ohio
R. D. Bennett Silver Spring, Md.
R. L. Biesele Dallas, Tex.
E. W. Boehne Cambridge, Mass.
D. S. Bridgman New York, N. Y.
M. S. Coover Ames, Iowa
W. C. DuVall Boulder, Colo.
A. W. Friend Princeton, N. J.
H. E. Hartig Minneapolis, Minn.
A. R. Hellwarth Detroit, Mich.
T. C. Lloyd Springfield, Ohio
K. B. McEachron, Jr. Schenectady, N. Y.
E. W. Morris Los Angeles, Calif.
H. A. Peterson Madison, Wis.
Walther Richter West Allis, Wis.
E. M. Strong Ithaca, N. Y.
B. R. Teare, Jr. Pittsburgh, Pa.
G. F. Tracy Toronto, Ontario, Canada
E. A. Walker Arlington, Va.
S. Reid Warren Philadelphia, Pa.

Lamme Medal

J. H. Berry Norfolk, Va.
T. H. Morgan Worcester, Mass.
L. A. Umansky Schenectady, N. Y.
(Terms expire July 31, 1951)
C. B. Jolliffe Princeton, N. J.
A. H. Kehoe, *Chairman* New York, N. Y.
J. B. MacNeill East Pittsburgh, Pa.
(Terms expire July 31, 1952)
W. J. Barrett Newark, N. J.
L. L. Bosch Boston, Mass.
Walther Richter West Allis, Wis.
(Terms expire July 31, 1953)

Management

A. C. Monteith, *Chairman;* Westinghouse Electric Corporation, 306 Fourth Avenue, Pittsburgh, Pa.
C. J. Beller, *Vice-Chairman,* Cleveland Electric Illuminating Company, 75 Public Square, Cleveland 13, Ohio
P. L. Alger Schenectady, N. Y.
K. P. Applegate Hartford, Conn.
R. D. Bennett Silver Spring, Md.
F. W. Bush Milwaukee, Wis.
W. L. Cisler Detroit, Mich.
E. E. Hill New York, N. Y.
E. L. Moreland Boston, Mass.
H. A. Peterson New York, N. Y.
D. A. Quarles New York, N. Y.
F. M. Roberts Schenectady, N. Y.
D. D. Smalley San Francisco, Calif.

Prizes, Award of Institute

J. J. Orr, *Chairman;* United States Rubber Company, 1230 Avenue of the Americas, New York 20, N. Y.
Edward C. Day, *Secretary* AIEE Headquarters
H. A. Affel Murray Hill, N. J.
J. C. Aydelott Erie, Pa.
Gordon S. Brown Cambridge, Mass.
W. R. Brownlee Jackson, Mich.
M. J. Kelly New York, N. Y.
A. E. Knowlton New York, N. Y.
K. B. McEachron Pittsfield, Mass.
G. W. Scott, Jr. Lancaster, Pa.
Arthur Bessey Smith Chicago, Ill.
S. D. Summers Washington, D. C.
H. M. Turner New Haven, Conn.
L. A. Umansky Schenectady, N. Y.
C. H. Willis Princeton, N. J.
Harold Winograd Milwaukee, Wis.

Registration of Engineers

Elgin B. Robertson, *Chairman;* P. O. Box 745, Dallas 1, Tex.
S. W. Anderson Lexington, Va.
J. M. Flanigen Atlanta, Ga.
J. H. Foote Jackson, Mich.
N. L. Freeman Schenectady, N. Y.
Ward Harrison Cleveland, Ohio
J. E. Hobson Stanford, Calif.
J. T. Hood Tacoma, Wash.
C. C. Knipmeyer Terre Haute, Ind.
K. B. McEachron Pittsfield, Mass.
E. W. Oesterreich Pittsburgh, Pa.
L. M. Robertson Denver, Colo.
E. W. Seeger Milwaukee, Wis.
R. W. Sorensen Pasadena, Calif.
P. G. Wallace Dallas, Tex.
R. G. Warner New Haven, Conn.
E. R. Whitehead Chicago, Ill.

Student Branches

F. O. McMillan, *Chairman;* Oregon State College, Corvallis, Oreg.
J. S. Antel, Jr. Washington, D. C.
E. J. Ballard, Jr. Lincoln, Neb.
Sterling Beckwith Milwaukee, Wis.
H. F. Cooke Syracuse, N. Y.
H. S. Dixon Fargo, N. D.

Division on Communication and Electronics
H. E. Farrer New York, N. Y.
F. E. Harrell Cleveland, Ohio
J. J. Pilliod New York, N. Y.
Division on Power
I. W. Gross New York, N. Y.
E. B. Paxton Schenectady, N. Y.

Industry Committee on Interior Wiring Design
M. M. Brandon New York, N. Y.
L. C. Peterman New York, N. Y.

Joint Committee for Development of Statistical Applications in Engineering and Manufacturing
W. P. Dobson Toronto, Ontario, Canada

National Fire Protection Association, Electrical Section
Robin Beach Brooklyn, N. Y.
W. B. Kouwenhoven Baltimore, Md.

AIEE Technical Subcommittees—1950–51

Communication Division

Communication Switching Systems

No subcommittees

Radio Communications Systems

Mobile Radio Subcommittee

A. C. Dickieson, *Chairman;* Bell Telephone Laboratories, Inc., 463 West Street, New York 14, N. Y.
C. M. Backer — Clifton, N. J.
I. F. Byrnes — New York, N. Y.
G. E. Dodrill — Washington, D. C.
J. W. Kearney — Mineola, N. Y.
L. P. Morris — Chicago, Ill.
David Talley — New York, N. Y.

Point-to-Point Radio Subcommittee

E. D. Becken, *Chairman;* R.C.A. Communications, Inc., 66 Broad Street, New York 4, N. Y.
R. D. Campbell — New York, N. Y.
H. P. Corwith — New York, N. Y.
Edward Daskam, Jr. — New York, N. Y.
G. E. Dodrill — Washington, D. C.
L. W. Gregory — Baltimore, Md.
D. D. Grieg — Nutley, N. J.
S. C. Leyland — Newark, N. J.

Special Communications Applications

Electro-Acoustics Subcommittee

R. B. Vaile, Jr., *Chairman;* Standard University, Stanford Research Institute, Stanford, Calif.
I. F. Byrnes — New York, N. Y.
L. C. Holmes — Rochester, N. Y.
H. H. Spencer — Camden, N. J.

Railroad Communications Subcommittee

W. D. Hailes, *Chairman;* General Railway Signal Company, 801 West Avenue, Rochester 11, N. Y.
G. W. Baughman — Swissvale, Pa.
L. E. Kearney — New York, N. Y.
R. H. Kline — Baltimore, Md.
Newton Monk — New York, N. Y.

Special Activities Subcommittee

A. J. Warner, *Chairman;* Federal Telecommunication Laboratories, 500 Washington Avenue, Nutley 10, N. J.
Melville Eastham — Cambridge, Mass.
R. H. Kline — Baltimore, Md.
Newton Monk — New York, N. Y.
H. H. Spencer — Camden, N. J.

Telegraph Systems

Facsimile Subcommittee

R. E. Mathes, *Chairman;* Gray Research and Development Company, Inc., 16–30 Arbor Street, Hartford 1, Conn.
A. G. Cooley — New York, N. Y.
W. G. H. Finch — Washington, D. C.
J. V. L. Hogan — New York, N. Y.
Grosvenor Hotchkiss — New York, N. Y.
J. R. Krock — Washington, D. C.

Television and Aural Broadcasting Systems

No subcommittees

Wire Communications Systems

No subcommittees

General Applications Division

Air Transportation

Aircraft Electrical Rotating Machinery Subcommittee

L. R. Larson, *Chairman;* Naval Research Laboratory, Washington, D. C.
J. W. Allen — Teterboro, N. J.
J. B. Crockford — Lima, Ohio
William Fell — Cleveland, Ohio
S. H. Hanville, Jr. — Washington, D. C.
R. D. Jones — Fort Wayne, Ind.
Paul Lebenbaum, Jr. — Lynn, Mass.
G. W. Sherman — Dayton, Ohio
R. R. Smith — Baltimore, Md.

Aircraft Electrical Systems Subcommittee

G. W. Almassy, *Chairman;* General Electric Company, 6900 South Stanford Avenue, Los Angeles 1, Calif.
J. W. Allen — Teterboro, N. J.
Phil. Binderman — Washington, D. C.
H. B. Bunce — East Pittsburgh, Pa.
L. M. Cobb — Johnsville, Pa.
D. W. Exner — Seattle, Wash.
H. L. Hildebrandt — Dayton, Ohio
C. S. Milliken — Burbank, Calif.
W. F. Moore — Schenectady, N. Y.
G. A. Phillips — Schenectady, N. Y.
V. O. Ray — Los Angeles, Calif.
D. H. Scott — Washington, D. C.
A. J. Snyder — Tulsa, Okla.
A. F. Trumbull — Santa Monica, Calif.

Principles of Altitude Rating of Electrical Apparatus Subcommittee

Karl Martinez, *Chairman;* Boeing Airplane Company, Plant 1, Seattle, Wash.
J. W. Allen — Teterboro, N. J.
S. H. Hanville, Jr. — Washington, D. C.
V. C. Holloway — Washington, D. C.
J. G. Hutton — Schenectady, N. Y.
C. A. Maple — Dayton, Ohio
R. A. Rugge — Grand Rapids, Mich.

Aircraft Electrical Control, Protective Devices and Cable Subcommittee

B. O. Austin, *Chairman;* Aviation Engineering Department, Westinghouse Electric Corporation, Lima, Ohio
Earl Barlow — Baltimore, Md.
E. E. Magee — Dayton, Ohio
R. A. Millermaster — Milwaukee, Wis.
H. S. Moore — New Haven, Conn.
W. F. Moore — Schenectady, N. Y.
J. Ottmar — Attleboro, Mass.
Milton Schach — Washington, D. C.
Omar Wally — Cleveland, Ohio
W. W. West — New York, N. Y.

Domestic and Commercial Applications

Electric Heating of Homes and Heat Pumps Subcommittee

J. C. Beckett, *Chairman* (West); Westx Electric Heater Company, 390 First Street, San Francisco 5, Calif.
T. C. Johnson, *Chairman* (East); General Electric Company, 5 Lawrence Street, Bloomfield, N. J.

Domestic Appliances Subcommittee

C. R. Reid, *Chairman;* Engineering Laboratories, The Hoover Company, North Canton, Ohio

Land Transportation

Heavy Traction Electrification Data Subcommittee

L. W. Birch, *Chairman;* Ohio Brass Company, Mansfield, Ohio
H. F. Brown — New Haven, Conn.
A. G. Oehler — New York, N. Y.
R. A. Williamson — Erie, Pa.
G. M. Woods — East Pittsburgh, Pa.

Projects:
(1). Catenary overhead systems
(2). Third rail systems
(3). Electric locomotives
(4). Substations
(5). Power supply

The personnel of the projects is as follows: (1) and (2). L. W. Birch, *Chairman,* Ohio Brass Company, Mansfield, Ohio; H. F. Brown, New Haven, Conn.
(3), (4), and (5). A. G. Oehler, New York, N. Y.; R. A. Williamson, Erie, Pa.; G. M. Woods, East Pittsburgh, Pa.

Heavy Traction Papers and Plans Subcommittee

H. F. Brown, *Chairman;* New York, New Haven, and Hartford Railroad, Railroad Station, New Haven, Conn.
W. A. Brecht — East Pittsburgh, Pa.
R. L. Kimball — New York, N. Y.

Light Traction Papers and Plans Subcommittee

G. M. Woods, *Chairman;* Industry Engineering Department, Westinghouse Electric Corporation, East Pittsburgh, Pa.
H. R. Blomquist — Providence, R. I.
D. L. Smith — Highwood, Ill.

Subcommittee on Revision of AIEE Standard Number 16 (Electric Railway Control Apparatus) ASA C48

R. A. Williamson, *Chairman;* Railroad Rolling Stock Division of Locomotive and Car Equipments Divisions, General Electric Company, Erie, Pa.
P. H. Hatch — New Haven, Conn.
J. G. Inglis — Toronto, Ontario, Canada
G. M. Woods — East Pittsburgh, Pa.

Marine Transportation

Power Generation Subcommittee

Clarence Lynn, *Chairman;* Westinghouse Electric Corporation, East Pittsburgh, Pa.
W. B. Armstrong — Washington, D. C.
H. C. Coleman — East Pittsburgh, Pa.
L. M. Goldsmith — Philadelphia, Pa.
W. E. Jacobsen — Schenectady, N. Y.
E. H. Stivender — Milwaukee, Wis.
O. A. Wilde — Chester, Pa.

Power Application Subcommittee

L. M. Goldsmith, *Chairman;* Atlantic Refining Company, 260 South Broad Street, Philadelphia, Pa.
W. B. Armstrong — Washington, D. C.
H. C. Coleman — East Pittsburgh, Pa.
W. E. Jacobsen — Schenectady, N. Y.
J. E. Jones — Milwaukee, Wis.
Clarence Lynn — East Pittsburgh, Pa.
E. H. Stivender — Milwaukee, Wis.

Wires and Cables Subcommittee

W. N. Zippler, *Chairman;* Gibbs and Cox, Inc., 1 Broadway, New York 4, N. Y.
P. J. DuMont — New York, N. Y.
J. B. Feder — Washington, D. C.
A. R. Gatewood — New York, N. Y.
W. E. Jacobsen — Schenectady, N. Y.
V. W. Mayer — Washington, D. C.
W. H. Reed — New York, N. Y.

Switchboards and Control Subcommittee

H. C. Coleman, *Chairman;* Westinghouse Electric Corporation, East Pittsburgh, Pa.
P. J. DuMont — New York, N. Y.
H. F. Harvey, Jr. — Newport News, Va.
J. E. Jones — Milwaukee, Wis.
C. Krommenhock — Brooklyn, N. Y.
J. D. Shuster — Quincy, Mass.
E. H. Stivender — Milwaukee, Wis.

Distribution Subcommittee

H. F. Harvey, Jr., *Chairman;* Newport News Shipbuilding and Dry Dock Company, Newport News, Va.
W. B. Armstrong — Washington, D. C.
A. R. Gatewood — New York, N. Y.
E. A. Geary — Camden, N. J.
L. M. Goldsmith — Philadelphia, Pa.
P. A. Guise — New York, N. Y.
V. W. Mayer — Washington, D. C.
W. N. Zippler — New York, N. Y.

Fittings and Appliances Subcommittee

V. W. Mayer, *Chairman;* United States Maritime Commission, Technical Division, United States Department of Commerce Building, Washington, D. C.
P. J. DuMont — New York, N. Y.
J. B. Feder — Washington, D. C.
R. W. Frost — Amesbury, Mass.
E. A. Geary — Camden, N. J.
P. A. Guise — New York, N. Y.
H. F. Harvey, Jr. — Newport News, Va.
E. M. Rothen — New York, N. Y.
J. D. Shuster — Quincy, Mass.
O. A. Wilde — Chester, Pa.

Communications and Alarm Subcommittee

W. H. Reed, *Chairman;* Bruce Electric Company, 196 West Houston Street, New York 14, N. Y.
R. W. Frost — Amesbury, Mass.
A. R. Gatewood — New York, N. Y.
E. A. Geary — Camden, N. J.
C. Krommenhock — Brooklyn, N. Y.
S. N. Mead — Amesbury, Mass.
E. M. Rothen — New York, N. Y.
J. D. Shuster — Quincy, Mass.
C. W. Souder — Great Neck, N. Y.

Navigation Equipment Subcommittee

S. N. Mead, *Chairman;* Sig-Trans, Inc., Haverhill Road, Amesbury, Mass.
R. W. Frost — Amesbury, Mass.
P. A. Guise — New York, N. Y.
C. Krommenhock — Brooklyn, N. Y.
E. M. Rothen — New York, N. Y.
G. W. Souder — Great Neck, N. Y.

Publicity, Personnel, and History Subcommittee

W. H. Reed, *Chairman;* Bruce Electric Company, 196 West Houston Street, New York 14, N. Y.
H. F. Harvey, Jr. — Newport News, Va.

Editing Subcommittee

W. N. Zippler, *Chairman;* Gibbs and Cox, Inc., 1 Broadway, New York 4, N. Y.
J. B. Feder — Washington, D. C.
H. F. Harvey, Jr. — Newport News, Va.
W. H. Reed — New York, N. Y.

International Standardization Subcommittee

A. R. Gatewood, *Chairman;* American Bureau of Shipping, 45 Broad Street, New York 4, N. Y.
H. C. Coleman — East Pittsburgh, Pa.
H. F. Harvey, Jr. — Newport News, Va.
W. N. Zippler — New York, N. Y.

Production and Application of Light

Nomenclature of Electronic Lamps Subcommittee

R. C. Putnam, *Chairman;* Case Institute of Technology, Cleveland, Ohio
G. S. Evans — Bloomfield, N. J.
L. R. Keiffer — Cleveland, Ohio
T. C. Sargent — Salem, Mass.

Industry Division

Chemical, Electrochemical and Electrothermal Applications

Arc Furnaces and Electrothermal Processes Subcommittee

E. H. Browning, Jr., *Chairman;* Industry Engineering Department 10-L, Westinghouse Electric Corporation, East Pittsburgh, Pa.
F. V. Andreae — Chattanooga, Tenn.
W. L. Bundy — Wilson Dam, Ala.
R. A. Geiselman — East Pittsburgh, Pa.
E. A. Hanff — Pittsburgh, Pa.
A. R. Olzrogge — Schenectady, N. Y.
E. Scheick — New York, N. Y.
H. H. Zielinski — Schenectady, N. Y.

Cathodic Protection Subcommittee

R. M. Wainwright, *Chairman;* College of

Engineering, University of Illinois, Urbana, Ill.
A. E. Archambault New York, N. Y.
J. D. Brance Houston, Tex.
A. S. Brooks Newark, N. J.
Guy Corfield Los Angeles, Calif.
G. C. Cox Charleston, W. Va.
I. A. Dennison Washington, D. C.
I. C. Dietze Los Angeles, Calif.
L. J. Gorman New York, N. Y.
T. G. Hieronymus Kansas City, Mo.
R. J. Kuhn New Orleans, La.
D. H. Levy Dallas, Tex.
R. W. Linney Oklahoma City, Okla.
F. J. Mollerus Richland, Wash.
R. L. Rayner Detroit, Mich.
H. W. Wahlquist New York, N. Y.

ELECTROLYTIC PROCESSES SUBCOMMITTEE

W. E. Gutzwiller, *Chairman;* Allis-Chalmers Manufacturing Company, Milwaukee, Wis.
Felix Glass Freeport, Tex.
J. D. Harper Alcoa, Tenn.
H. E. Houck Wilmington, Del.
F. L. Kaestle Schenectady, N. Y.
Rollin Kennard Butte, Mont.
F. L. Lawton Montreal, Quebec, Canada
G. H. Orcutt Wyandotte, Mich.
Waldo Porter Vancouver, Wash.
G. B. Scherer Oakland, Calif.
Joel Tompkins Massena, N. Y.

PETROLEUM REFINING AND PRODUCTION SUBCOMMITTEE

Lester Goldsmith, *Chairman;* Atlantic Refining Company, 260 South Broad Street, Philadelphia 1, Pa.
H. J. Appel New York, N. Y.
E. C. Benjamin New York, N. Y.
W. H. Dickinson Elizabeth, N. J.
J. B. Glasby Philadelphia, Pa.
E. L. Hoyle East Chicago, Ind.
D. H. Levy Dallas, Tex.
E. L. Nopper Philadelphia, Pa.

STORAGE BATTERIES SUBCOMMITTEE

H. C. Riggs, *Chairman;* Electric Storage Battery Company, 19th and Allegheny Avenue, Philadelphia 32, Pa.
J. D. Hunnsberger Trenton, N. J.
L. A. Murray Providence, R. I.
E. T. Rummel Cleveland, Ohio
J. J. Unger Cleveland, Ohio
K. A. Vaughn Depew, N. Y.
H. H. Zielinski Schenectady, N. Y.

CHEMICAL INDUSTRIES SUBCOMMITTEE

L. W. Roush, *Chairman;* Union Carbide and Carbon Corporation, South Charleston, W. Va.
Felix Glass Freeport, Tex.
E. M. Hansford Montgomery, W. Va.
J. A. Horacek Fairport Harbor, Ohio
H. E. Houck Wilmington, Del.
M. A. Hyde East Pittsburgh, Pa.
S. J. Rosch Hastings-on-Hudson, N. Y.

Electric Heating

RADIANT HEATING SUBCOMMITTEE

I. J. Barber, *Chairman;* Fostoria Pressed Steel Corporation, 1945 Bradner Street, Fostoria, Ohio
E. J. Bates Dayton, Ohio
Earl Benson Boston, Mass.
P. O. Blackmore Newark, N. J.
P. H. Bowman Chicago, Ill.
A. H. Canada Schenectady, N. Y.
C. S. Cogger Nutley, N. J.
P. H. Goodell Detroit, Mich.
J. C. Handy Baltimore, Md.
S. G. Hibben Bloomfield, N. J.
W. F. Hickes Foxboro, Mass.
J. E. Johanson St. Louis, Mo.
J. E. Kolb Pittsburgh, Pa.
E. A. Linsday Cleveland, Ohio
R. C. Machler Philadelphia, Pa.
C. L. Raylor Detroit, Mich.
C. E. Russell Philadelphia, Pa.
Lawrence Stout St. Louis, Mo.
W. H. Wannamaker Philadelphia, Pa.

INDUCTION AND DIELECTRIC HEATING SUBCOMMITTEE

W. C. Rudd, *Chairman;* 68 Lansdowne Drive, Larchmont, N. Y.
R. M. Baker Baltimore, Md.
G. P. Bosomworth Akron, Ohio
E. W. Chapin Laurel, Md.
F. T. Chesnut Trenton, N. J.
L. M. Duryee Waterbury, Conn.
J. E. Eiselein Camden, N. J.
C. W. Frick Schenectady, N. Y.
W. H. Hickok Louisville, Ky.
R. J. Hunn Wilmington, Del.
T. P. Kinn Baltimore, Md.
G. W. Klingaman Camden, N. J.
Eugene Mittleman Chicago, Ill.
William Paulin Toronto, Ont., Canada
G. W. Scott, Jr. Lancaster, Pa.
R. S. Tucker New York, N. Y.
J. T. Vaughan Cleveland, Ohio
D. E. Watts Syracuse, N. Y.
Otto Weitmann New York, N. Y.

RADIATION MEASUREMENTS ABOVE 200 MEGACYCLES SUBCOMMITTEE

R. M. Baker, *Chairman;* Westinghouse Electric Corporation, 2519 Wilkens Avenue, Baltimore 3, Md.
H. H. Beiser Fort Monmouth, N. J.
Marvin Bock Waltham, Mass.
E. W. Chapin Laurel, Md.
H. E. Disger Washington, D. C.
J. E. Eiselein Camden, N. J.
C. W. Frick Schenectady, N. Y.
J. C. Handy Baltimore, Md.
Paul Hines Newton, Mass.
W. L. Roberts East Pittsburgh, Pa.
Ralph M. Showers Philadelphia, Pa.
H. E. Sorrows Wheaton, Md.
A. J. Vadasz Syracuse, N. Y.

Electric Welding

POWER SUPPLY FOR RESISTANCE WELDING MACHINES SUBCOMMITTEE

C. N. Clark, *Chairman;* Duquesne Light Company, 435 Sixth Avenue, Pittsburgh, Pa.
N. A. Kieb, *Vice-Chairman;* Detroit, Mich.
E. L. Bailey Highland Park, Mich.
W. K. Boice Schenectady, N. Y.
W. G. Bostwick Cincinnati, Ohio
W. W. Brumby Toronto, Ontario, Canada
J. F. Deffenbaugh Warren, Ohio
S. W. Luther Detroit, Mich.
R. S. Phair Philadelphia, Pa.
C. E. Smith Warren, Ohio
J. L. Solomon Chicago, Ill.
C. B. Stadum Buffalo, N. Y.
H. W. Tietze Newark, N. J.
H. R. Wall Jackson, Mich.
Myron Zucker Royal Oak, Mich.

FUNDAMENTAL ELECTRIC ARC RESEARCH SUBCOMMITTEE

R. C. McMaster, *Chairman;* Battelle Memorial Institute, 505 King Avenue, Columbus 1, Ohio
J. H. Chyle Milwaukee, Wis.
J. D. Cobine Schenectady, N. Y.
Wolfgang Finkelnburg Fort Belvoir, Va.
W. J. Greene Murray Hill, N. J.
Julius Heuschkel East Pittsburgh, Pa.
W. B. Kouwenhoven Baltimore, Md.
Robert Krieger Columbus, Ohio
J. M. Parks Chicago, Ill.
S. F. Radtke Newport, Del.
R. E. Somers Bethlehem, Pa.
E. H. Wilhelm Annapolis, Md.
L. P. Winsor Troy, N. Y.

Feedback Control Systems

TERMINOLOGY AND NOMENCLATURE SUBCOMMITTEE

F. E. Crever, *Chairman;* Atomic Power Division, General Electric Company, Schenectady, N. Y.
W. R. Ahrendt College Park, Md.
H. W. Cory Milwaukee, Wis.
Paul Travers Cambridge, Mass.
A. J. Williams, Jr. Philadelphia, Pa.

General Industry Applications

MACHINE TOOLS SUBCOMMITTEE

D. R. Percival, *Chairman;* Machinery Electrification Inc., 98 Union Street, Worcester, Mass.
B. T. Anderson Rockford, Ill.
R. W. Brown Windsor, Vt.
J. M. Delfs Schenectady, N. Y.
R. T. Fenn Springfield, Vt.
L. W. Herchenroeder Pittsburgh, Pa.
J. J. Jaeger West Hartford, Conn.
E. F. Mekelburg Milwaukee, Wis.
W. J. Piper Springfield, Vt.
S. Rice Worcester, Mass.
E. J. Rivoire Cincinnati, Ohio
R. E. Stroppel Cincinnati, Ohio
W. B. Wigton Cincinnati, Ohio
T. A. Wetzel Milwaukee, Wis.

MATERIALS HANDLING SUBCOMMITTEE

S. P. Blakeman, *Chairman;* Haughton Elevator Company, 1725 Fairmount Avenue, Philadelphia, Pa.
F. W. Ate Philadelphia, Pa.
E. L. Blankenbeker Pittsburgh, Pa.
A. R. Dunne Port Hope, Ontario, Canada
D. C. Gray St. Paul, Minn.
C. P. Hamilton Schenectady, N. Y.
E. M. Hays Pittsburgh, Pa.
W. O. Land Philadelphia, Pa.
G. N. Meyers Philadelphia, Pa.
Fred A. Miller Wilmington, Del.

PULP AND PAPER INDUSTRY SUBCOMMITTEE

W. B. Baker, *Chairman;* Westinghouse Electric Corporation, Industrial Engineering Division, East Pittsburgh, Pa.
H. B. Barrow Atlanta, Ga.
G. C. Ehemann Rittman, Ohio
G. W. Knapp Schenectady, N. Y.
E. K. Murphy New York, N. Y.
E. H. Overby Savannah, Ga.
H. A. Rose Seattle, Wash.
J. L. Van Nort Cleveland, Ohio

RUBBER AND PLASTICS INDUSTRIES SUBCOMMITTEE

H. F. Snyder, *Chairman;* Goodyear Tire and Rubber Company, 1144 East Market Street, Akron, Ohio
A. T. Bacheler Buffalo, N. Y.
L. T. Blalock Dallas, Texas
B. J. Dalton Schenectady, N. Y.
K. W. John Detroit, Mich
G. V. Kulligren Akron, Ohio
J. F. Moore Toronto, Ontario, Canada
H. R. Neighbours Mishawaka, Ind.
R. G. Rudrow Wilmington, Del.
W. J. Secrest Akron, Ohio
R. E. Seddon Wilmington, Del.
A. G. Seifried Akron, Ohio
H. L. Smith New York, N. Y.
W. S. Watkins Willoughby, Ohio
B. H. Zacherle Philadelphia, Pa.

TEXTILE INDUSTRY SUBCOMMITTEE

R. J. Demartini, *Chairman,* General Electric Company, Industry Engineering Division, Schenectady 5, N. Y.
A. T. Bacheler Buffalo, N. Y.
S. A. Bobe Atlanta, Ga.
Swaffield Cowan Charlotte, N. C.
R. B. Flowers Atlanta, Ga.
A. W. Frankenfield Wilmington, Del.
H. Haley Philadelphia, Pa.
L. T. Jester Boston, Mass.
A. F. Lukens West Lynn, Mass.
V. P. Sepavich Worcester, Mass.
F. D. Snyder Boston, Mass.
H. C. Uhl Sylacauga, Alabama

Industrial Control

BIBLIOGRAPHY SUBCOMMITTEE

R. W. Jones, *Chairman;* Department of Electrical Engineering, Northwestern University, Evanston, Ill.
W. H. Elliott Milwaukee, Wis.
E. E. Moyer Troy, N. Y.
J. W. Picking Cleveland, Ohio
Walter Schaelchlin East Pittsburgh, Pa.

ELECTRONIC CONTROL SUBCOMMITTEE

H. L. Palmer, *Chairman;* General Electric Company, 1 River Road, Schenectady 5, N. Y.
F. T. Bailey Buffalo, N. Y.
H. B. Black Ampere, N. J.
L. H. Dee Schenectady, N. Y.
W. H. Elliot Milwaukee, Wis.
William Few Cleveland, Ohio
E. W. Hutton Schenectady, N. Y.
L. U. G. Kelling Schenectady, N. Y.
M. H. A. Lindsay New York, N. Y.
E. B. McDowell Schenectady, N. Y.
F. O. Nottingham Lafayette, Ind.
J. W. Picking Cleveland, Ohio
L. C. Poole Detroit, Mich.
V. J. Porter Philadelphia, Pa.
K. P. Puchlowski Pittsburgh, Pa.
W. G. Roman Buffalo, N. Y.
C. A. Schurr Cleveland, Ohio
H. I. Stanback Milwaukee, Wis.
G. F. Stark Baltimore, Md.
B. B. Stuart Waltham, Mass.
C. M. Summers Fort Wayne, Ind.
B. F. Tellkamp Milwaukee, Wis.

Working Groups:

(1). Electronic Control of D-C Motors
J. W. Picking, *Chairman;* Reliance Electric and Engineering Company, 1049–1088 Ivanhoe Road, Cleveland 10, Ohio
H. B. Black Ampere, N. J.
L. H. Dee Schenectady, N. Y.
W. H. Elliot Milwaukee, Wis.
William Few Cleveland, Ohio
L. C. Poole Detroit, Mich.
W. G. Roman Buffalo, N. Y.
H. I. Stanback Milwaukee, Wis.
B. B. Stuart Waltham, Mass.
B. F. Tellkamp Milwaukee, Wis.

(2). Photoelectric Pickup Systems
L. U. G. Kelling, *Chairman;* General Electric Company, 1 River Road, Schenectady 5, N. Y.
F. T. Bailey Buffalo, N. Y.
M. H. A. Lindsay New York, N. Y.
E. M. Pritchard Boston, Mass.
L. L. Worner Rankin, Ill.

(3). Electronic Relaying Devices
E. B. McDowell, *Chairman;* General Electric Company, 1 River Road, Schenectady 5, N. Y.
C. A. Schurr Cleveland, Ohio
B. F. Tellkamp Milwaukee, Wis.

(4). Electronic Control of A-C Power
E. W. Hutton, *Chairman;* General Electric Company, 1 River Road, Schenectady 5, N. Y.
H. B. Black Ampere, N. J.
W. H. Elliot Milwaukee, Wis.
W. G. Roman Buffalo, N. Y.
G. F. Stark Baltimore, Md.
B. F. Tellkamp Milwaukee, Wis.

REGULATORS AND FEEDBACK SYSTEMS SUBCOMMITTEE

O. W. Livingston, *Chairman;* Electronics and Regulator Control Engineering Division, General Electric Company, 1 River Road, Schenectady 5, N. Y.
H. B. Black Ampere, N. J.
S. L. Burgwin Buffalo, N. Y.
E. T. Davis Philadelphia, Pa.
W. H. Elliot Milwaukee, Wis.
William Few Cleveland, Ohio
J. W. Picking Cleveland, Ohio
B. F. Tellkamp Milwaukee, Wis.

STANDARDS SUBCOMMITTEE

J. O'Connor, *Chairman;* Associate Editor, *Power,* McGraw-Hill Publishing Company, 330 West 42nd Street, New York 18, N. Y.
E. L. Bailey Detroit, Mich.
J. E. Gahagan Binghamton, N. Y.
J. A. Gienger Rochester, N. Y.
F. Y. Grepe Toronto, Ontario, Canada
R. W. Kowitz Dearborn, Mich.
L. H. Matthias Milwaukee, Wis.
F. E. Strauss Oakland, Calif.

TEST CODES SUBCOMMITTEE

C. T. Evans, *Chairman;* Cutler-Hammer, Inc., 315 North 12th Street, Milwaukee, Wis.
D. K. Frost Rockford, Ill.
B. W. Jones Schenectady, N. Y.
H. E. Nason Chicago, Ill.
W. E. Pakala East Pittsburgh, Pa.
H. E. Rhoads Schenectady, N. Y.
C. A. Schaefer Milwaukee, Wis.

Industrial Power Systems

EXECUTIVE SUBCOMMITTEE

Main Committee Officers:
J. S. Gault, *Chairman;* Electrical Engineering Department, University of Michigan, Ann Arbor, Mich.
H. G. Barnett, *Vice-Chairman* East Pittsburgh, Pa.
S. A. Warner, *Secretary* New York, N. Y.

Subcommittee Chairmen:
H. G. Barnett East Pittsburgh, Pa.
D. I. Beeman Schenectady, N. Y.
C. R. Johnson New York, N. Y.
A. E. Marshall St. Louis, Mo.
T. O. Sweatt New York, N. Y.
B. F. Thomas, Jr. New York, N. Y.

POWER SUPPLY SUBCOMMITTEE

A. E. Marshall, *Chairman;* Monsanto Chemical Company, 1700 South 2nd Street, St. Louis 4, Mo.
A. J. Claes East St. Louis, Ill.
R. T. Woodruff St. Louis, Mo.

Distribution Systems for Industrial Plants Subcommittee

H. G. Barnett, *Chairman;* Westinghouse Electric Corporation, East Pittsburgh, Pa.
J.P.E. Arberry Pittsburgh, Pa.
D. L. Beeman Schenectady, N. Y.
D. D. Douglass Oakland, Calif.
W. S. Gordon, Jr. Tacoma, Wash.
C. R. Johnson New York, N. Y.
C. M. Lathrop Elizabeth, N. J.
S. W. Luther Detroit, Mich.
J. E. Mellett Atlanta, Ga.
Dick Ray Tulsa, Okla.
C. C. Saunders Wilmington, Del.
R. C. Waldron Passaic, N. J.
R. M. Wilson, Jr. Schenectady, N. Y.
T. O. Zittel Lackawanna, N. Y.

Distribution Systems for Commercial Buildings Subcommittee

B. F. Thomas, Jr., *Chairman;* N. A. Lougee and Company, 120 Broadway, New York 5, N. Y.
Allan Coggeshall New York, N. Y.
L. C. McCullough New York, N. Y.
A. C. Youngson New York, N. Y.

Characteristics of Loads Subcommittee

T. O. Sweatt, *Chairman;* Wearn, Vreeland, Carlson and Sweatt, Inc., 43 Exchange Place, New York 5, N. Y.
V. E. Dodson Seattle, Wash.
K. K. Falk South Bend, Ind.
J. D. Harper Alcoa, Tenn.
C. M. Lathrop Elizabeth, N. J.
C. C. Saunders Wilmington, Del.
W. J. Secrest Akron, Ohio
T. O. Zittel Lackawanna, N. Y.

Industrial Grounding Subcommittee

D. L. Beeman, *Chairman;* General Electric Company, Schenectady 5, N. Y.
H. H. Angel Bethlehem, Pa.
J. E. Arberry Pittsburgh, Pa.
K. M. Bausch San Francisco, Calif.
Fred Heller New York, N. Y.
E. M. Hunter Schenectady, N. Y.
L. W. Roush South Charleston, W. Va.
C. C. Saunders Wilmington, Del.
J. M. Schmidt Baytown, Texas
T. O. Sweatt New York, N. Y.
H. B. Thacker East Pittsburgh, Pa.
B. F. Thomas, Jr. New York, N. Y.
S. A. Warner New York, N. Y.

Codes and Standards Subcommittee

C. R. Johnson, *Chairman;* The Port of New York Authority, Engineering Department, 111 Eighth Avenue, New York 11, N. Y.
L. W. McCullough New York, N. Y.

Mining and Metal Industry

Metal Industries Subcommittee

W. R. Harris, *Chairman;* Westinghouse Electric Corporation, Department 10-L, East Pittsburgh, Pa.
J. E. Arberry Pittsburgh, Pa.
H. W. Bakeborn Newark, Ohio
F. W. Cramer Pittsburgh, Pa.
Sam Ein Chicago, Ill.
R. H. Ellis Pittsburgh, Pa.
Cecil Farrow Cleveland, Ohio
Lanier Greer Cleveland, Ohio
L. N. Grier Pittsburgh, Pa.
W. E. Miller Schenectady, N. Y.
B. E. Price New York, N. Y.
E. G. Schlup Middletown, Ohio
F. O. Schnure Sparrows Point, Md.
Victor Siegfried Worcester, Mass.
H. I. Stanback Milwaukee, Wis.
J. R. Wickey Cleveland, Ohio

Mining Subcommittee

J. J. Fitzgibbon, *Chairman;* General Electric Company, 306 MacCorkle Avenue, Charleston 28, W. Va.
J. E. Breth Bessemer, Ala.
Graham Bright Pittsburgh, Pa.
A. B. Chafets Carlsbad, N. Mex.
R. J. Corfield Garfield, Utah
E. W. Davis Cambridge, Mass.
J. M. Downie Erie, Pa.
J. H. Edwards New York, N. Y.
C. L. Gust Lead, S. Dak.
L. H. Harrison Birmingham, Ala.
J. G. Ivy Chicago, Ill.
L. H. James Scranton, Pa.
G. F. Johnson Michigan City, Ind.
J. Z. Linsenmeyer East Pittsburgh, Pa.
R. C. McMaster Columbus, Ohio
A. C. Muir Philadelphia, Pa.
H. P. Musser Charleston, W. Va.
M. G. Myers, Jr. Boston, Mass.
F. C. Nicholson Wilkes-Barre, Pa.
C. A. Poppino Phoenix, Arizona
B. E. Rector East Pittsburgh, Pa.
D. E. Renshaw Chicago, Ill.
L. W. Roush South Charleston, W. Va.
O. J. Swanson Gary, W. Va.
C. L. Tyler Irwin, Pa.
T. R. Weichel Wilkes-Barre, Pa.
W. G. Willson Phoenix, Arizona
C. O. Wood Chicago, Ill.

Power Division

Carrier Current

Subcommittee for Preparation of a General Interest Paper on Carrier Current

M. H. Wood, *Chairman;* Westinghouse Electric Corporation, Electronics and X-Ray Division, 2519 Wilkens Avenue, Baltimore 3, Md.
S. C. Bartlett New York, N. Y.
J. D. Booth Baltimore, Md.
L. F. Kennedy Schenectady, N. Y.

Subcommittee to Report on Application Guidance for Carrier Current

D. M. MacGregor, *Chairman;* Ebasco Services, Inc., 2 Rector Street, New York 6, N. Y.
C. W. Boadway Toronto, Ontario, Canada
T. D. Talmage Chattanooga, Tenn.

Methods of Measurement Subcommittee

E. W. Kenefake, *Chairman;* General Electric Company, Electronics Department, Syracuse, N. Y.
S. C. Bartlett New York, N. Y.
C. W. Boadway Toronto, Ontario, Canada
M. H. Wood Baltimore, Md.

High-Frequency Characteristics of Power Equipment Subcommittee

S. C. Leyland, *Chairman;* Westinghouse Electric Corporation, 95 Orange Street, Newark 2, N. J.
T. A. Cramer Schenectady, N. Y.

Carrier Current Characteristics of Transmission Lines and Systems Subcommittee

T. D. Talmage, *Chairman;* Kellogg Switchboard and Supply Company, 6650 Cicero Avenue, Chicago 38, Ill.
W. H. Blankmeyer Butte, Mont.
R. C. Ericson Hammond, Ind.
W. J. Googe Shreveport, La.
L. E. Ludekens Los Angeles, Calif.

Long Life Tubes Subcommittee

L. G. Eaton, *Chairman;* New England Power Service Company, 441 Stuart Street, Boston 16, Mass.
R. W. Beckwith Syracuse, N. Y.
L. F. Ferri Elyria, Ohio
Samuel Lubin Washington, D. C.
M. H. Wood Baltimore, Md.

Use of Microwave Equipment for Relaying, Telemetering, and Supervisory Control Subcommittee

S. C. Leyland, *Chairman;* Westinghouse Electric Corporation, 95 Orange Street, Newark 2, N. J.

Operating Experience With Carrier Current Relaying Channels Subcommittee

O. A. Starcke, *Chairman;* Kansas City Power and Light Company, Box 679, Kansas City, Mo.
T. A. Cramer Schenectady, N. Y.
J. R. Curtin Portland, Oreg.
W. J. Googe Shreveport, La.
V. J. Hayes Waterbury, Conn.
H. W. Lenzner Newark, N. J.
L. E. Ludekens Los Angeles, Calif.
B. W. Storer Chicago, Ill.
Mead Warren, Jr. Alcoa, Tenn.

Insulated Conductors

Administration Subcommittee

Herman Halperin, *Chairman;* Commonwealth Edison Company, 72 West Adams Street, Chicago 90, Ill.
V. A. Sheals, *Vice-Chairman* Schenectady, N. Y.
C. T. Hatcher, *Secretary* New York, N. Y.
L. F. Hickernell Hastings-on-Hudson, N. Y.

Subcommittee Chairmen:
H. W. Acock Trenton, N. J.
W. A. Del Mar Yonkers, N. Y.
G. H. Fiedler Rochester, N. Y.
L. E. Fogg Phillipsdale, R. I.
M. W. Ghen Pittsburgh, Pa.
L. I. Komives Detroit, Mich.
W. T. Peirce Worcester, Mass.
R. S. Peterson Chicago, Ill.
G. M. L. Sommerman Evanston, Ill.
Gordon Thompson New York, N. Y.
H. H. Watson Bridgeport, Conn.

Standards and Publications Subcommittee

L. E. Fogg, *Chairman;* Kennecott Wire and Cable Company, Phillipsdale, R. I
A. S. Brookes Newark, N. J.
M. H. McGrath New York, N. Y.
V. A. Sheals Schenectady, N. Y.
H. D. Short Toronto, Ontario, Canada
C. W. Zimmerer New York, N. Y.

Cable Characteristics Subcommittee

W. A. Del Mar, *Chairman;* Phelps Dodge Copper Products Company, Habirshaw Cable and Wire Division, Yonkers, N. Y.
E. D. Bent Montreal, Quebec, Canada
C. T. Hatcher New York, N. Y.
A. H. Kidder Philadelphia, Pa.
C. G. Mansfield Los Angeles, Calif.
M. H. McGrath New York, N. Y.
J. H. Neher Philadelphia, Pa.
G. B. Shanklin Schenectady, N. Y.
F. V. Smith Chicago, Ill.
E. R. Thomas New York, N. Y.
R. J. Wiseman Passaic, N. J.
F. O. Wollaston Vancouver, B. C., Canada
R. K. Woodson Kansas City, Mo.

Conductors Subcommittee

G. W. Acock, *Chairman;* J. A. Roebling's Sons, 640 South Broad Street, Trenton, N. J.
L. E. Fogg Phillipsdale, R. I.
R. C. Waldron Passaic, N. J.
G. W. Zink Yonkers, N. Y.

Insulations Subcommittee

G. M. L. Sommerman, *Chairman;* Department of Electrical Engineering, Northwestern Technological Institute, Evanston, Ill.
J. C. Balbaugh Cambridge, Mass.
C. E. Betzer Chicago, Ill.
F. M. Clark Pittsfield, Mass.
A. S. Dana Seymour, Conn.
E. W. Greenfield Hastings-on-Hudson, N. Y.
Thorstein Larsen Baltimore, Md.
E. L. Lotz Irvington, N. J.
R. B. McKinley Bridgeport, Conn.
J. D. Piper Detroit, Mich.
R. A. Schatzel Rome, N. Y.
E. G. Sturdevant Bristol, R. I.
A. J. Warner Nutley, N. J.
K. S. Wyatt Yonkers, N. Y.

Sheaths and Coverings Subcommittee

G. H. Fiedler, *Chairman;* Rochester Gas and Electric Company, Rochester, N. Y.
C. F. Avila Boston, Mass.
C. E. Betzer Chicago, Ill.
Andrew Bodicky St. Louis, Mo.
A. S. Brookes Newark, N. J.
A. H. Kidder Philadelphia, Pa.
F. E. Kulman New York, N. Y.
A. D. Pettee Perth Amboy, N. J.
V. A. Sheals Schenectady, N. Y.
R. C. Waldron Passaic, N. J.
G. W. Zink Yonkers, N. Y.

Cable Supply Systems Subcommittee

L. I. Komives, *Chairman;* Detroit Edison Company, 2000—2d Avenue, Detroit 26, Mich.
C. F. Avila Boston, Mass.
T. J. Brosnan Buffalo, N. Y.
W. R. Bullard New York, N. Y.
H. W. Clark Washington, D. C.
D. M. Farnham Montreal, Quebec, Canada
J. D. Frantz Portland, Oreg.
C. T. Hatcher New York, N. Y.
M. J. Lowenberg Boston, Mass.
A. D. Pettee Perth Amboy, N. J.
C. S. Schifreen Philadelphia, Pa.
G. B. Shanklin Schenectady, N. Y.
H. D. Short Toronto, Ontario, Canada
C. F. Titus Jacksonville, Fla.
R. J. Wiseman Passaic, N. J.
F. O. Wollaston Vancouver, B. C., Canada
K. S. Wyatt Yonkers, N. Y.

Utilization Wiring Systems Subcommittee

H. H. Watson, *Chairman;* General Electric Company, 1285 Boston Avenue, Bridgeport 2, Conn.
E. L. Bailey Detroit, Mich.
H. G. Barnett East Pittsburgh, Pa.
A. L. Barrett Franklin, Pa.
C. M. Boardman Pittsburgh, Pa.
T. P. Branch Washington, D. C.
C. A. Finkel Passaic, N. J.
R. W. Foster Canton, N. C.
F. S. Glass Freeport, Texas
Lester Goldsmith Philadelphia, Pa.
J. E. Huguelet Detroit, Mich.
M. J. Lowenberg Boston, Mass.
J. B. MacLean New York, N. Y.
S. J. Roach Hastings-on-Hudson, N. Y.
R. A. Schatzel Rome, N. Y.
J. S. Waddington Brockville, Ontario, Canada
C. W. Zimmerer New York, N. Y.

Special-Purpose Cable Subcommittee

W. T. Peirce, *Chairman;* American Steel and Wire Company, Worcester, Mass.
G. W. Acock Trenton, N. J.
J. F. Atkinson Washington, D. C.
A. L. Barrett Franklin, Pa.
E. D. Bent Montreal, Quebec, Canada
E. W. Davis Cambridge, Mass.
R. A. Hopkins Knoxville, Tenn.
J. E. Huguelet Detroit, Mich.
R. H. Kolks Cincinnati, Ohio
R. B. McKinley Bridgeport, Conn.
M. L. Perry Kansas City, Mo.
F. V. Smith Chicago, Ill.
E. G. Sturdevant Bristol, R. I.
C. F. Titus Jacksonville, Fla.
R. K. Woodson Kansas City, Mo.
W. N. Zippler New York, N. Y.
G. W. Zink Yonkers, N. Y.

Accessories Subcommittee

M. W. Ghen, *Chairman;* Duquesne Light Company, 1241 Reedsdale Street, N. S. Pittsburgh 33, Pa.
P. N. Borworth Pittsfield, Mass.
C. Christensen Melrose Park, Ill.
C. D. Eash Jackson, Mich.
J. D. Frantz Portland, Oreg.
G. G. Grissinger East Pittsburgh, Pa.
Fred Heller New York, N. Y.
J. E. Johnson Philadelphia, Pa.
R. H. Kolks Cincinnati, Ohio
L. E. Leinbach Detroit, Mich.
E. L. Lotz Irvington, N. J.
H. E. Martin Brooklyn, N. Y.
R. E. Morse New York, N. Y.
J. H. Nicholas Chicago, Ill.
Lawrence Palmer Seattle, Wash.
M. L. Perry, Jr. Kansas City, Mo.
F. P. West New York, N. Y.
D. S. Young Toronto, Ont., Canada
S. Zyak Schenectady, N. Y.

Structures Subcommittee

R. S. Peterson, *Chairman;* Commonwealth Edison Company, 72 West Adams Street, Chicago 90, Ill.
M. J. Andrews Los Angeles, Calif.

C. E. Baugh San Francisco, Calif.
Andrew Bodicky St. Louis, Mo.
T. J. Brennan Buffalo, N. Y.
H. W. Clark Washington, D. C.
C. D. Eash Jackson, Mich.
G. H. Fiedler Rochester, N. Y.
Lawrence Palmer Seattle, Wash.
L. G. Smith Baltimore, Md.
F. P. West New York, N. Y.
R. K. Woodson Kansas City, Mo.

TESTS AND MEASUREMENTS SUBCOMMITTEE

Gordon Thompson, *Chairman;* Electrical Testing Laboratories, Inc., 2 West End Avenue, New York 21, N. Y.
J. C. Balsbaugh Cambridge, Mass.
A. L. Brownlee Chicago, Ill.
A. S. Dana Seymour, Conn.
E. W. Davis Cambridge, Mass.
W. A. Del Mar Yonkers, N. Y.
E. W. Greenfield Hastings-on-Hudson, N. Y.
Thorstein Larsen Baltimore, Md.
J. C. Parker Memphis, Tenn.
G. M. L. Sommerman Evanston, Ill.
R. F. Tener Washington, D. C.
E. R. Thomas New York, N. Y.
R. C. Waldron Passaic, N. J.
C. W. Zimmerer New York, N. Y.

Power Generation

PRIME MOVERS SUBCOMMITTEE

B. G. A. Skrotzki, *Chairman;* Associate Editor, *Power*, 330 West 42d Street, New York 18, N. Y.
J. A. Brooks New York, N. Y.
E. P. Bryant Los Angeles, Calif.
A. D. Caskey Chicago, Ill.
Michael Pope New York, N. Y.
C. S. Randall Washington, D. C.
R. R. Wiener Boston, Mass.

SPEED GOVERNING SUBCOMMITTEE

J. B. McClure, *Chairman;* General Electric Company, Central Station Engineering Division, Schenectady 5, N. Y.
R. E. Appleyard Milwaukee, Wis.
C. P. Almon, Jr. Chattanooga, Tenn.
R. M. Beville Chicago, Ill.
A. P. Hayward Pittsburgh, Pa.
T. H. Mawson Birmingham, Ala.
G. H. McDaniel New York, N. Y.
F. L. Reinmann Michigan City, Ind.

EXCITATION SYSTEMS SUBCOMMITTEE

A. J. Krupy, *Chairman;* Commonwealth Edison Company, 72 West Adams Street, Chicago 90, Ill.
J. B. McClure, *Vice-Chairman*
Schenectady, N. Y.
J. E. Barkle, Jr. East Pittsburgh, Pa.
E. F. Dissmeyer Jackson, Mich.
Alex. Dovjikov Portland, Oreg.
C. B. Fontaine, Jr. Lynn, Mass.
L. A. Kilgore East Pittsburgh, Pa.
J. H. Kinghorn New York, N. Y.
H. A. P. Langstaff Pittsburgh, Pa.
T. B. Montgomery Milwaukee, Wis.
F. D. Troxel Chicago, Ill.
R. L. Witzke East Pittsburgh, Pa.

STATION DESIGN SUBCOMMITTEE

H. R. Harris, *Chairman;* The Detroit Edison Company, 2000—2d Avenue, Detroit 26, Mich.
H. E. Deardorff Dayton, Ohio
C. A. Harrington Cleveland, Ohio
D. R. Pattison Johnstown, Pa.
W. W. Perry Binghamton, N. Y.
R. R. Wiener Boston, Mass.

HYDROELECTRIC SYSTEMS SUBCOMMITTEE

F. L. Lawton, *Chairman;* Aluminum Laboratories, Ltd., 1800 Sun Life Building, Montreal, Quebec, Canada
S. M. Denton Denver, Colo.
J. T. Madill Arvida, Quebec, Canada
E. F. Maryatt San Francisco, Calif.
A. L. Pollard Seattle, Wash.
G. R. Woodman Los Angeles, Calif.

PACIFIC COAST SUBCOMMITTEE

E. P. Bryant, *Chairman;* Department of Water and Power, City of Los Angeles, 207 South Broadway, Los Angeles 12, Calif.
S. M. Denton Denver, Colo.
Alex Dovjikov Portland, Oreg.
F. F. Maryatt San Francisco, Calif.
A. L. Pollard Seattle, Wash.
G. R. Woodman Los Angeles, Calif.

Protective Devices

FAULT LIMITING DEVICES SUBCOMMITTEE

E. G. Norell, *Chairman;* Sargent and Lundy, 140 South Dearborn Street, Chicago 3, Ill.
J. P. Barron Dallas, Texas
V. J. Cisna Chattanooga, Tenn.
J. A. Coleman Boston, Mass.
G. B. Dodds Pittsburgh, Pa.
E. T. B. Gross Chicago, Ill.
W. D. Hardaway Denver, Colo.
H. W. Hartsell Jackson, Mich.
E. M. Hunter Schenectady, N. Y.
P. A. Jeanne New York, N. Y.
A. A. Johnson East Pittsburgh, Pa.
W. A. Lewis, Jr. Chicago, Ill.
F. R. Longley Springfield, Mass.
Cort Lowerison Los Angeles, Calif.
Corbett McLean Portland, Oreg.
H. D. Ruger Sparrows Point, Md.
O. L. Sidenfaden Los Angeles, Calif.
W. T. Smith Arlington, Va.
S. S. Watkins New York, N. Y.

Project 1: Application Guide on Methods of Grounding Transmission Systems
E. N. Hunter, *Chairman*
Schenectady, N. Y.
H. W. Hartsell Jackson, Mich.
A. A. Johnson East Pittsburgh, Pa.
R. E. Neidig Reading, Pa.

Project 2: Application Guide for the Grounding of Synchronous Generator Systems
A. A. Johnson, *Chairman*
East Pittsburgh, Pa.
E. M. Hunter Schenectady, N. Y.
D. M. MacGregor New York, N. Y.
W. E. Marter Pittsburgh, Pa.
E. G. Norell Chicago, Ill.
W. T. Smith Arlington, Va.

Project 3: Bibliography of Literature on Grounding
E. T. B. Gross, *Chairman* Chicago, Ill.
J. E. Clem Schenectady, N. Y.

Project 4: Guide for Application of Ground-Fault Neutralizers
J. E. Clem, *Chairman* Schenectady, N. Y.
H. H. Brown Cedar Rapids, Iowa
S. S. Cook Sharon, Pa.
N. E. Dillow Schenectady, N. Y.
W. D. Hardaway Denver, Colo.
R. E. Neidig Reading, Pa.
P. B. Speer Minneapolis, Minn.

Project 5: Power System Fault Control
F. R. Longley, *Chairman* Springfield, Mass.
J. O. Coleman Boston, Mass.
F. H. Kierstead Pittsfield, Mass.
L. B. LeVeneste Chicago, Ill.
H. F. Lindemuth New York, N. Y.
E. L. Michelson Chicago, Ill.
L. E. Sauer Sharon, Pa.

LIGHTNING PROTECTIVE DEVICES SUBCOMMITTEE

E. H. Yonkers, *Chairman;* Joslyn Manufacturing and Supply Company, 969 West 37th Place, Chicago 9, Ill.
J. E. Clem Schenectady, N. Y.
L. M. Connors Toronto, Ont., Canada
H. A. Cornelius Chicago, Ill.
F. M. Defandorf Washington, D. C.
G. K. Ditlow Washington, D. C.
J. R. Eaton Lafayette, Ind.
T. I. Eldridge Philadelphia, Pa.
I. W. Gross New York, N. Y.
E. H. Grosser Chicago, Ill.
H. W. Hartsell Jackson, Mich.
T. H. Mawson Birmingham, Ala.
W. A. McMorris Pittsfield, Mass.
A. M. Opsahl East Pittsburgh, Pa.
H. L. Rorden Portland, Oreg.
A. H. Schirmer New York, N. Y.
H. O. Stoelting So. Milwaukee, Wis.
J. M. Towner Baltimore, Md.

Project 1: Application Guide of Methods for Lightning Protection of Substations
H. A. Cornelius, *Chairman* Chicago, Ill.
Harris Barber Boston, Mass.
H. W. Hartsell Jackson, Mich.
S. B. Howard Pittsfield, Mass.
E. L. Jarrett Pittsburgh, Pa.
R. H. Mertz Detroit, Mich.
A. M. Opsahl East Pittsburgh Pa.
E. R. Whitehead Chicago, Ill.

Project 10: Recovery Voltage Characteristics of Distribution Systems
R. L. Witzke, *Chairman*
East Pittsburgh, Pa.
G. K. Ditlow Washington, D. C.
I. B. Johnson Schenectady, N. Y.
L. M. Olmstead Pittsburgh, Pa.
M. A. Pulster Baltimore, Md.

CO-ORDINATION OF INSULATION SUBCOMMITTEE

J. E. Clem, *Chairman;* Central Station Engineering Division, General Electric Company, Schenectady 5, N. Y.

Relays

PROJECT COMMITTEE ON BIBLIOGRAPHY OF RELAY LITERATURE

E. T. B. Gross, *Chairman* and *Sponsor;* Illinois Institute of Technology, 3300 Federal Street, Chicago 16, Ill.
S. Goldsmith Cincinnati, Ohio
C. E. Parks Indianapolis, Ind.
C. L. Smith Rochester, N. Y.

PROJECT COMMITTEE ON GENERATOR PROTECTION

H. R. Paxson, *Chairman* and *Sponsor;* Philadelphia Electric Company, 900 Sansom Street, Philadelphia 5, Pa.
L. L. Draper Los Angeles, Calif.
L. L. Fountain East Pittsburgh, Pa.
E. T. B. Gross Chicago, Ill.
B. C. Hicks Montreal, Quebec, Canada
L. F. Kennedy Schenectady, N. Y.
S. C. Leyland Newark, N. J.
H. F. Lindemuth New York, N. Y.
W. E. Marter Pittsburgh, Pa.
J. B. McClure Schenectady, N. Y.
A. J. McConnell Schenectady, N. Y.
C. E. Parks Indianapolis, Ind.
F. C. Poage New York, N. Y.
L. T. Rosenberg Milwaukee, Wis.
H. P. Sleeper Newark, N. J.
C. L. Smith Rochester, N. Y.

PROJECT COMMITTEE ON CO-ORDINATION OF CONSTRUCTION AND PROTECTION OF DISTRIBUTION CIRCUITS (JOINT WITH DISTRIBUTION SUBCOMMITTEE AND EDISON ELECTRIC INSTITUTE)

G. B. Dodds, AIEE *Chairman* and *Sponsor;* Duquesne Light Company, 435 Sixth Avenue, Pittsburgh 19, Pa.
R. O. Askey Chicago, Ill.
G. G. Auer Schenectady, N. Y.
T. J. Brennan Buffalo, N. Y.
Harold Cole Detroit, Mich.
W. B. Fisk, Jr. New York, N. Y.
C. L. Headley Baltimore, Md.
Cort Lowerison Los Angeles, Calif.
H. F. Ortman St. Louis, Mo.
C. L. Smith Rochester, N. Y.
C. J. Beller, EEI *Chairman* and *Sponsor;* Cleveland Electric Illuminating Company, 75 Public Square, Cleveland 1, Ohio
G. H. Fiedler Rochester, N. Y.
G. E. Dean Newark, N. J.
W. P. Holben Pittsburgh, Pa.
A. L. Malmstrom Detroit, Mich.

PROJECT COMMITTEE ON REVISION OF STANDARDS FOR POWER RELAYS

S. C. Leyland, *Chairman* and *Sponsor;* Westinghouse Electric Corporation, 95 Orange Street, Newark 2, N. J.
R. E. Cordray Philadelphia, Pa.
V. L. Cox Philadelphia, Pa.
L. L. Fountain East Pittsburgh, Pa.
W. A. Lewis Chicago, Ill.
J. R. Linders Cleveland, Ohio
E. L. Michelson Chicago, Ill.
W. A. Morgan Denver, Colo.
H. P. Sleeper Newark, N. J.
G. S. Steeb Buffalo, N. Y.

PROJECT COMMITTEE ON TRANSMISSION-LINE PROTECTION

J. H. Kinghorn, *Chairman* and *Sponsor;* American Gas and Electric Service Corporation, 30 Church Street, New York 7, N. Y.
L. J. Audlin Syracuse, N. Y.
J. E. Barkle, Jr. East Pittsburgh, Pa.
W. R. Brownlee Jackson, Mich.
B. C. Hicks Montreal, Quebec, Canada
W. A. Lewis Chicago, Ill.
W. E. Marter Pittsburgh, Pa.
A. J. McConnell Schenectady, N. Y.
M. S. Merritt Chattanooga, Tenn.
E. L. Michelson Chicago, Ill.
C. E. Parks Indianapolis, Ind.
K. N. Reardon Pittsburgh, Pa.

PROJECT COMMITTEE ON ELECTRONIC RELAY APPLICATIONS

A. J. McConnell, *Chairman* and *Sponsor;* General Electric Company, Schenectady 5, N. Y.
J. E. Barkle, Jr. East Pittsburgh, Pa.
R. J. Cooper Atlanta, Ga.
F. S. Fehr Reading, Pa.
L. F. Ferri Elyria, Ohio
E. L. Harder East Pittsburgh, Pa.
J. H. Kinghorn New York, N. Y.
D. M. MacGregor New York, N. Y.
E. L. Michelson Chicago, Ill.
E. G. Ratz Hamilton, Ontario, Canada

PROJECT COMMITTEE ON RELAYING OF INTERCONNECTIONS BETWEEN INDUSTRIAL AND UTILITY GENERATING SYSTEMS

K. N. Reardon, *Chairman* and *Sponsor;* West Penn Power Company, 14 Wood Street, Pittsburgh, Pa.
J. E. Barkle, Jr. East Pittsburgh, Pa.
G. E. Dana Binghamton, N. Y.
F. S. Fehr Reading, Pa.
T. R. Halman Detroit, Mich.
J. R. Linders Lakewood, Ohio

PROJECT COMMITTEE ON RELAYING PERFORMANCE OF CURRENT TRANSFORMERS (EMPHASIS ON HIGH IMPEDANCE SECONDARY TYPES)

W. E. Marter, *Chairman* and *Sponsor;* Duquesne Light Company, 435—6th Avenue, Pittsburgh 19, Pa.
J. E. Barkle East Pittsburgh, Pa.
J. E. Clem Schenectady, N. Y.
R. E. Cordray Philadelphia, Pa.
W. K. Dickinson Lynn, Mass.
T. R. Halman Detroit, Mich.
W. A. Lewis Chicago, Ill.
W. K. Sonnemann Newark, N. J.
E. C. Wentz Sharon, Pa.

PROJECT COMMITTEE ON REMOTE TRIPPING SCHEMES

H. P. Sleeper, *Chairman* and *Sponsor;* Public Service Gas and Electric Company, 80 Park Place, Newark 2, N. J.
J. L. Blackburn Newark, N. J.
M. A. Bostwick Portland, Oreg.
T. A. Cramer Schenectady, N. Y.
Sidney Goldsmith Cincinnati, Ohio
G. W. Hampe Chicago, Ill.
Y. J. Hayes Waterbury, Conn.
S. C. Leyland Newark, N. J.

PROJECT COMMITTEE ON PILOT WIRES

H. F. Lindemuth, *Chairman* and *Sponsor;* Consolidated Edison Company of New York, Inc., 4 Irving Place, New York 3, N. Y.
M. A. Bostwick Portland, Oreg.
J. L. Blackburn, Jr. Mineola, N. Y.
W. E. Marter Pittsburgh, Pa.
A. J. McConnell Schenectady, N. Y.
J. L. McKee New York, N. Y.
G. W. McKenna Philadelphia, Pa.
E. L. Michelson Chicago, Ill.
W. K. Sonnemann Newark N. J.

PROJECT COMMITTEE ON EFFECT OF SHOCK AND VIBRATION ON RELAYS

C. E. Asbury, *Chairman* and *Sponsor;* Commonwealth Services, Inc., 212 West Michigan Avenue, Jackson, Mich.
R. E. Cordray Philadelphia, Pa.
M. A. Faucett Urbana, Ill.
T. R. Halman Detroit, Mich.
H. F. Lindemuth New York, N. Y.
W. K. Sonnemann Newark, N. J.
G. S. Steeb Buffalo, N. Y.
R. I. Ward Chicago, Ill.

PROJECT COMMITTEE ON TEST METHODS

G. E. Dana, *Chairman* and *Sponsor;* New York State Electric and Gas Corporation, 62 Henry Street, Binghamton, N. Y.
R. E. Cordray Philadelphia, Pa.
L. F. Ferri Elyria, Ohio
T. R. Halman Detroit, Mich.
J. E. Lange Pittsburgh, Pa.
R. A. Larner Fort Worth, Texas

W. A. Morgan — Denver, Colo.
W. K. Sonnemann — Newark, N. J.

Rotating Machinery

Administrative Subcommittee

W. R. Heugh, *Chairman*, Reliance Electric and Engineering Company, 1068-1088 Ivanhoe Road, Cleveland 10, Ohio
C. G. Veinott, *Vice-Chairman* — Lima, Ohio
J. L. Fuller, *Secretary* — Cleveland, Ohio
R. E. Arnold — West Lynn, Mass.
B. H. Caldwell — Schenectady, N. Y.
James DeKiep — Minneapolis, Minn.
J. W. Jones — Philadelphia, Pa.
I. M. Levy — Dayton, Ohio
S. S. Wolff — St. Louis, Mo.

Synchronous Machinery Subcommittee

James DeKiep, *Chairman*; Electric Machinery Manufacturing Company, 1331 Tyler Street, Minneapolis 13, Minn.
Sterling Beckwith — Milwaukee, Wis.
J. F. Calvert — Evanston, Ill.
S. B. Crary — Schenectady, N. Y.
L. O. Dorfman — New York, N. Y.
E. L. Harder — East Pittsburgh, Pa.
J. W. Jones — Philadelphia, Pa.
C. E. Kilbourne — Schenectady, N. Y.
L. B. LeVesconte — Chicago, Ill.
M. R. Lory — East Pittsburgh, Pa.
J. G. Noest — New York, N. Y.
E. J. Pollard — Ridgway, Pa.
J. H. Vivian — Los Angeles, Calif.
S. S. Wolff — St. Louis, Mo.

Induction Machinery Subcommittee

S. S. Wolff, *Chairman*; Century Electric Company, 1806 Pine Street, St. Louis 3, Mo.
R. E. Arnold — West Lynn, Mass.
E. L. Bailey — Detroit, Mich.
E. C. Barnes — Cleveland, Ohio
C. F. Cameron — Stillwater, Okla.
S. F. Henderson — Buffalo, N. Y.
C. J. Koch — Schenectady, N. Y.
I. M. Levy — Dayton, Ohio
T. C. Lloyd — Springfield, Ohio
R. C. Moore — Milwaukee, Wis.
J. G. Noest — New York, N. Y.
C. P. Potter — St. Louis, Mo.
F. C. Rushing — Buffalo, N. Y.
F. H. Trickey — Finderne, N. J.
F. M. Winterhalter — Norwood, Ohio

D-C Machinery Subcommittee

B. H. Caldwell, *Chairman*; General Electric Company, 1 River Road, Schenectady 5, N. Y.
M. A. Baker — Fort Wayne, Ind.
C. F. Cobb — Cincinnati, Ohio
A. G. Darling — Schenectady, N. Y.
W. H. Fifer — Washington, D. C.
Lanier Greer — Cleveland, Ohio
C. B. Hathaway — Buffalo, N. Y.
L. H. Hildebrandt — Dayton, Ohio
H. E. Koenig — Urbana, Ill.
R. Lamborn — Erie, Pa.
Paul Lebenbaum, Jr. — Lynn, Mass.
Clarence Lynn — East Pittsburgh, Pa.
T. J. Martin — Seattle, Wash.
A. T. McClinton — Washington, D. C.
W. E. Meserve — Ithaca, N. Y.
J. G. Noest — New York, N. Y.
L. G. Opel — Buffalo, N. Y.
J. H. Schneider — Ridgway, Pa.
J. F. Sellers — Milwaukee, Wis.
F. H. Trickey — Finderne, N. J.
S. S. Wolff — St. Louis, Mo.

Single-Phase and Fractional-Horsepower Subcommittee

I. M. Levy, *Chairman*; Delco Products Division, General Motors Corporation, Dayton, Ohio
W. R. Appleman — Dayton, Ohio
C. F. Cameron — Stillwater, Okla.
J. S. Gault — Ann Arbor, Mich.
E. E. Kimberly — Columbus, Ohio
T. C. Lloyd — Springfield, Ohio
C. F. Miller — Baltimore, Md.
R. F. Munier — St. Louis, Mo.
C. P. Potter — St. Louis, Mo.
L. C. Schaefer — Lima, Ohio
M. L. Schmidt — Fort Wayne, Ind.
F. H. Trickey — Finderne, N. J.
C. G. Veinott — Lima, Ohio
S. S. Wolff — St. Louis, Mo.

Test Code Subcommittee

R. E. Arnold, *Chairman*; General Electric Company, 920 Western Avenue, West Lynn, Mass.
J. L. Fuller — Cleveland, Ohio
J. S. Gault — Ann Arbor, Mich.
Clarence Lynn — East Pittsburgh, Pa.
H. C. Marcroft — Lancaster, Pa.
R. F. Munier — St. Louis, Mo.
E. B. Paxton — Schenectady, N. Y.
E. I. Pollard — Ridgway, Pa.

Insulation Subcommittee

J. W. Jones, *Chairman*; Philadelphia Electric Company, Edison Building, Philadelphia 5, Pa.
L. J. Berberich — East Pittsburgh, Pa.
E. B. Curdts — Philadelphia, Pa.
E. F. Dissmeyer — Jackson, Mich.
Orville Fawcett — Pittsburgh, Pa.
D. D. Higgins — Chicago, Ill.
J. L. Kuehlthau — Milwaukee, Wis.
H. C. Marcroft — Lancaster, Pa.
G. L. Moses — East Pittsburgh, Pa.
E. I. Pollard — Ridgway, Pa.
R. H. Povey — Belmont, Mass.
V. E. Schloseberg — East Chicago, Ind.
J. B. Swering — Hartford, Conn.
H. R. Tomlinson — Boston, Mass.
A. L. Van Emden — Washington, D. C.
R. W. Wieseman — Schenectady, N. Y.

Substations

Executive Subcommittee

R. C. Ericson, *Chairman*; Northern Indiana Public Service Company, 5265 Hohman Avenue, Hammond, Ind.
M. V. Eardley — Los Angeles, Calif.
N. G. Larson — Chicago, Ill.
G. S. Lunge — Schenectady, N. Y.
M. E. Reagan — East Pittsburgh, Pa.
K. L. Wheeler — Cleveland, Ohio

Automatic and Supervisory Control Subcommittee

M. E. Reagan, *Chairman*; Switchboard Engineering Department, Westinghouse Electric Corporation, East Pittsburgh, Pa.
T. J. Allen — Atlanta, Ga.
Herman Bany — Philadelphia, Pa.
R. O. Bell — Milwaukee, Wis.
B. D. Dexter — San Francisco, Calif.
W. M. Larson — Minneapolis, Minn.
J. L. McKee — New York, N. Y.

Distribution and Conversion Substation Subcommittee

M. V. Eardley, *Chairman*; Department of Water and Power, City of Los Angeles, Los Angeles 54, Calif.
T. J. Allen — Atlanta, Ga.
Herman Bany — Philadelphia, Pa.
R. O. Bell — Milwaukee, Wis.
C. C. Crane — Madison, Wis.
G. P. Fallon — Baltimore, Md.
E. M. Hunter — Schenectady, N. Y.
I. S. Mendenhall — Detroit, Mich.

Transmission Substation Subcommittee

I. S. Mendenhall, *Chairman*; The Detroit Edison Company, 2000 Second Avenue, Detroit 26, Mich.
T. J. Allen — Atlanta, Ga.
Harris Barber — Boston, Mass.
F. J. Berger — Philadelphia, Pa.
H. P. Cadario — Toronto, Ontario, Canada
Marino Fraresso — Toronto, Ont., Canada
H. F. Gidlund — Denver, Colo.
E. M. Hunter — Schenectady, N. Y.
S. C. Killian — Chicago, Ill.
N. G. Larson — Chicago, Ill.
W. M. McCauley — Greenburg, Pa.
D. C. Millard — Denver, Colo.
J. H. Rixse, Jr. — Washington, D. C.
W. S. Scherring — Springfield, Mass.
R. F. Stevens — Portland Oreg.

Working Group on Device Function Numbers

Herman Bany, *Chairman*; General Electric Company, 6901 Elmwood Avenue, Philadelphia 42, Pa.
L. B. LeVesconte — Chicago, Ill.
M. E. Reagan — East Pittsburgh, Pa.
M. S. Schneider — Cincinnati, Ohio

Working Group on Substation Grounding Practice

H. F. Gidlund, *Chairman*; Public Service Company of Colorado, 810—15th Street, Denver 2, Colo.
F. J. Berger — Philadelphia, Pa.
M. K. Brown — Buffalo, N. Y.
F. R. Longley — Springfield, Mass.
J. M. Towner — Baltimore, Md.

Working Group on Rectifier Switchgear

M. E. Reagan, *Chairman*; Switchgear Engineering Department, Westinghouse Electric Corporation, East Pittsburgh, Pa.
D. C. Hoffman — Philadelphia, Pa.

Switchgear

Circuit Breaker Subcommittee

R. L. Webb, *Chairman*; Consolidated Edison Company of New York Inc., 4 Irving Place, New York 3, N. Y.
J. A. Elzi — Jackson, Mich.
R. M. Ferrill — Chattanooga, Tenn.
W. D. Hardaway — Denver, Colo.
A. W. Hill — East Pittsburgh, Pa.
M. H. Hobbs — East Pittsburgh, Pa.
C. L. Killgore — Denver, Colo.
F. A. Lane — New York, N. Y.
W. G. Lewis — Boston, Mass.
F. W. McCloska — Chicago, Ill.
W. J. McLachlan — Schenectady, N. Y.
A. Van Ryan — South Milwaukee, Wis.
J. H. Vivian — Los Angeles, Calif.
C. E. Winegartner — Cleveland, Ohio
J. D. Wood — Philadelphia, Pa.
J. C. Woods — Chicago, Ill.
B. W. Wyman — Philadelphia, Pa.

Working Groups:

(*1*). Automatic Circuit Reclosers

Anthony Van Ryan, *Chairman*; Line Material Company, Kyle Products Plant, 9th and Marion Avenues, South Milwaukee, Wis.
C. E. Asbury — Jackson, Mich.
L. L. Baird — Philadelphia, Pa.
Chase Hutchinson — New York, N. Y.
H. H. Rudd — Greensburg, Pa.
J. M. Wallace — East Pittsburgh, Pa.
C. E. Winegartner — Cleveland, Ohio

(*2*). Low-Voltage Air Circuit Breakers

J. D. Wood, *Chairman*; I.T.E. Circuit Breaker Company, 19th and Hamilton Streets, Philadelphia 30, Pa.
G. G. Grissinger — East Pittsburgh, Pa.
C. L. Killgore — Denver, Colo.
R. G. Meyerand — St. Louis, Mo.
V. E. Schloseberg — East Chicago, Ill.
J. W. Timmermaat, Jr. — Milwaukee, Wis.
J. C. Woods — Chicago, Ill.
B. W. Wyman — Philadelphia, Pa.
S. W. Zimmerman — Ithaca, N. Y.

(*3*). Power Circuit Breakers

A. W. Hill, *Chairman*; Westinghouse Electric Corporation, East Pittsburgh, Pa.
R. M. Bennett — Philadelphia, Pa.
J. A. Elzi — Jackson, Mich.
R. M. Ferrill — Chattanooga, Tenn.
S. B. Griscom — East Pittsburgh, Pa.
W. D. Hardaway — Denver, Colo.
C. L. Killgore — Denver, Colo.
W. G. Lewis — Boston, Mass.
J. H. Vivian — Los Angeles, Calif.
J. D. Wood — Philadelphia, Pa.
C. A. Woodrow — Schenectady, N. Y.

Switchgear Assemblies Subcommittee

C. P. West, *Chairman*; Westinghouse Electric Corporation, East Pittsburgh, Pa.
J. M. Geiger — Buffalo, N. Y.
C. L. Killgore — Denver, Colo.
M. G. Lewis — San Francisco, Calif.
F. W. McCloska — Chicago, Ill.
E. F. Miller — Davenport, Iowa
G. M. Reed — Philadelphia, Pa.
Garland Stamper — Dayton, Ohio
B. K. Sturgis — Philadelphia, Pa.
J. W. Timmerman, Jr. — Waukesha, Wis.
W. F. Wetmore — Detroit, Mich.

Switches, Fuses and Insulators Subcommittee

K. J. C. Falck, *Chairman*; Philadelphia Electric Company, 900 Sansom Street, Philadelphia 7, Pa.
T. E. Curtis — Hampton, Ga.
A. H. Powell — Philadelphia, Pa.
R. M. Smith — Greensburg, Pa.
J. M. Wallace — East Pittsburgh, Pa.
J. C. Woods — Chicago, Ill.

System Engineering

Administrative Subcommittee

Robert Brandt, *Chairman*; New England Power Company, 441 Stuart Street, Boston 16, Mass.
C. P. Almon, Jr. — Chattanooga, Tenn.
W. B. Fisk — New York, N. Y.
H. L. Harrington — Buffalo, N. Y.
C. B. Kelley — Des Moines, Iowa
H. A. Lott — Los Angeles, Calif.
O. W. Mans, Jr. — New York, N. Y.
G. B. Mayott — Hartford, Conn.
C. N. Metcalf — New York, N. Y.
C. W. Watchorn — Baltimore, Md.

System Planning Subcommittee

W. B. Fisk, *Chairman*; Consolidated Edison Company of New York, Inc., 4 Irving Place, New York 3, N. Y.
C. G. Adams — Schenectady, N. Y.
O. E. Charlton — Birmingham, Ala.
A. G. Dewars — Minneapolis, Minn.
A. P. Fugill — Detroit, Mich.
R. G. Hooke — Newark, N. J.
R. R. Jones — Chicago, Ill.
C. L. Killgore — Denver, Colo.
H. J. Klumb — Rochester, N. Y.
A. A. Kroseberg — Los Angeles, Calif.
R. F. Lawrence — East Pittsburgh, Pa.
W. H. Osterle — Pittsburgh, Pa.
H. P. St. Clair — New York, N. Y.
G. F. Switzer — Indianapolis, Ind.
J. J. Tesar — Cleveland, Ohio
D. C. Vaughan — Washington, D. C.
R. M. Walker — El Paso, Texas
Matthew Ward — Toronto, Ontario, Canada

System Operations Subcommittee

C. B. Kelley, *Chairman*; Interchange Power Service, P. O. Box 616, Des Moines, Iowa
F. A. Andrews — Baltimore, Md.
E. C. Brown — Hartford, Conn.
O. A. Demuth — Portland, Oreg.
G. D. Floyd — Toronto, Ontario, Canada
S. M. Hamill, Jr. — Cincinnati, Ohio
A. C. Hartranft — Philadelphia, Pa.
W. R. Johnson — San Francisco, Calif.
J. C. Jones — Portland, Oreg.
O. W. Mans, Jr. — New York, N. Y.
W. E. Montgomery — Los Angeles, Calif.
Noel Pike — Phoenix, Ariz.
G. M. Tatum — Richmond, Va.

System Economics Subcommittee

C. W. Watchorn, *Chairman*; Pennsylvania Water and Power Company, 1611 Lexington Building, Baltimore, Md.
E. C. Brown — Hartford, Conn.
E. E. George — New York, N. Y.
A. P. Hayward — Pittsburgh, Pa.
N. M. Lovell — Tucson, Ariz.
H. P. Peters — Atlanta, Ga.
H. W. Phillips — Philadelphia, Pa.
R. T. Purdy — Chicago, Ill.
J. A. Rose — Newark, N. J.
J. B. Ward — Lafayette, Ind.
A. L. Williams — Los Angeles, Calif.

System Controls Subcommittee

C. P. Almon, Jr., *Chairman*; Tennessee Valley Authority, Chattanooga 4, Tenn.
W. R. Brownlee — Jackson, Mich.
D. H. Cameron — Kansas City, Mo.
R. F. Lawrence — East Pittsburgh, Pa.
G. H. McDaniel — New York, N. Y.
C. N. Metcalf — New York, N. Y.
S. B. Morehouse — Philadelphia, Pa.
G. S. Whitlow — St. Louis, Mo.

Interconnection Contracts Subcommittee

C. W. Mayott, *Chairman*; Hartford Electric Light Company, 266 Pearl Street, Hartford, Conn.
Bradley Cozzens — Los Angeles, Calif.
E. D. Early — Birmingham, Ala.
E. E. George — New York, N. Y.
M. H. Lovelady — Corpus Christi, Tex.
G. H. McDaniel — New York, N. Y.

Transformers

Co-ordinated Study of Life of Transformer Insulation Subcommittee

J. L. Cantwell, *Chairman*; General Electric Company, 100 Woodlawn Avenue, Pittsfield, Mass.

C. E. Arntzen East Pittsburgh, Pa.
F. M. Clark Pittsfield, Mass.
J. F. Dexter Midland, Mich.
C. F. Hill East Pittsburgh, Pa.
Myron Kin Midland, Mich.
V. M. Montsinger Pittsfield, Mass.
T. D. Reimers New York, N. Y.
W. W. Satterlee Sharon, Pa.
W. M. Terry, Jr. Pittsburgh, Pa.
F. J. Vogel Chicago, Ill.
H. G. Zambell Pittsburgh, Pa.

INSTRUMENT TRANSFORMERS SUBCOMMITTEE

J. E. Clem, *Chairman;* Central Station Engineering Division, General Electric Company, Schenectady 5, N. Y.
Herman Bany Philadelphia, Pa.
J. H. Chiles Sharon, Pa.
R. E. Cordray Philadelphia, Pa.
F. E. Davis, Jr. Jackson, Mich.
K. J. C. Falck Philadelphia, Pa.
R. E. Franck Lynn, Mass.
J. M. Geiger Buffalo, N. Y.
T. R. Halman Detroit, Mich.
R. K. Huntington Rochester, N. Y.
L. F. Kennedy Schenectady, N. Y.
W. E. Marter Pittsburgh, Pa.
E. V. Sayles Jackson, Mich.
J. P. Scott St. Louis, Mo.
F. B. Silsbee Washington, D. C.
W. K. Sonnemann Newark, N. J.
W. M. Terry, Jr. Pittsburgh, Pa.
E. C. Wentz Sharon, Pa.
C. A. Woods East Pittsburgh, Pa.

AIEE PAPERS SUBCOMMITTEE

J. E. Clem, *Chairman;* Central Station Engineering Division, General Electric Company, Schenectady 5, N. Y.

MAGNETIZATION CHARACTERISTICS OF TRANSFORMERS SUBCOMMITTEE

J. E. Clem, *Chairman;* Central Station Engineering Divisions, General Electric Company, Schenectady 5, N. Y.
J. A. Elsi Jackson, Mich.
T. D. Gordy Pittsfield, Mass.
J. H. Kinghorn New York, N. Y.
W. E. Marter Pittsburgh, Pa.
A. J. Maslin Sharon, Pa.
A. H. Powell Philadelphia, Pa.
W. C. Sealey Milwaukee, Wis.
J. M. Wallace East Pittsburgh, Pa.

REVISION OF DIELECTRIC TESTS SUBCOMMITTEE

F. J. Vogel, *Chairman;* Illinois Institute of Technology, Chicago, Ill.
V. F. Christen St. Louis, Mo.
I. W. Gross New York, N. Y.
J. H. Hagenguth Pittsfield, Mass.
D. M. MacGregor New York, N. Y.
W. R. McCarty St. Louis, Mo.
J. R. Meador Pittsfield, Mass.
C. W. Miller Sharon, Pa.
V. M. Montsinger Pittsfield, Mass.
W. C. Sealey Milwaukee, Wis.
W. L. Teague Sharon, Pa.

GUIDES FOR OPERATION AND MAINTENANCE OF DRY-TYPE TRANSFORMERS WITH CLASS B INSULATION

J. A. Adams, *Chairman;* Philadelphia Electric Company, 900 Sansom Street, Philadelphia 5, Pa.
G. J. Johnston Pittsburgh, Pa.
T. D. Reimers New York, N. Y.
T. E. Rodhouse Pittsfield, Mass.
W. W. Satterlee Sharon, Pa.
H. H. Wagner Cannonsburg, Pa.
C. E. Winegartner Cleveland, Ohio

CO-ORDINATION OF INSULATION SUBCOMMITTEE

J. E. Clem, *Chairman;* Central Station Engineering Division, General Electric Company, Schenectady 5, N. Y.

ELECTRONIC POWER CONVERTERS SUBCOMMITTEE

W. C. Sealey, *Chairman;* Allis-Chalmers Manufacturing Company, Post Office Box 512, Milwaukee 1, Wis.

METHODS OF MAKING TEMPERATURE TESTS ON TRANSFORMERS SUBCOMMITTEE

J. E. Clem, *Chairman;* General Electric Company, Central Station Engineering Division, Schenectady 5, N. Y.
J. A. Adams Philadelphia, Pa.
M. F. Beavers Pittsfield, Mass.
M. K. Brown Buffalo, N. Y.
H. B. Keath St. Louis, Mo.
A. J. Maslin Sharon, Pa.
W. H. Mutschler Pittsburgh, Pa.

POWER FACTOR MEASUREMENTS SUBCOMMITTEE

J. B. Hodtum, *Chairman;* Allis-Chalmers Manufacturing Company, N. S. Station, Pittsburgh 33, Pa.

AUDIBLE NOISE IN TRANSFORMERS SUBCOMMITTEE

J. H. Chiles, *Chairman;* Westinghouse Electric Corporation, Transformer Engineering Department, Sharon, Pa.
J. E. Clem Schenectady, N. Y.
T. D. Gordy Pittsfield, Mass.
D. L. Levine Chicago, Ill.
A. J. Maslin Sharon, Pa.
T. D. Reimers New York, N. Y.
J. M. Towner Baltimore, Md.

HOT SPOT TEMPERATURE RISE OF CLASS B REACTORS SUBCOMMITTEE

D. L. Levine, *Chairman;* Commonwealth Edison Company, 72 West Adams Street, Chicago 90, Ill.
F. H. Kiersted Pittsfield, Mass.
L. E. Sauer Sharon, Pa.

PERMISSIBLE MAXIMUM OIL TEMPERATURE IN SERVICE SUBCOMMITTEE

M. H. Pratt, *Chairman;* Niagara Mohawk Power Corporation, 300 Erie Boulevard, Syracuse 2, N. Y.
J. G. Ford Sharon, Pa.
J. R. Meador Pittsfield, Mass.

THERMAL RATINGS AS AFFECTED BY ENCLOSURES SUBCOMMITTEE

A. A. Johnson, *Chairman;* Westinghouse Electric Corporation, East Pittsburgh, Pa.
J. E. Clem Schenectady, N. Y.
W. G. James Sharon, Pa.
E. K. Kane Pittsfield, Mass.
D. L. Levine Chicago, Ill.
W. C. Sealey Milwaukee, Wis.

A STUDY ON POSSIBLE SLIDING SCALE RELATION BETWEEN IMPEDANCE AND SHORT-CIRCUIT TIME FOR TRANSFORMERS AND REACTORS SUBCOMMITTEE
(Personnel to be selected)

Transmission and Distribution

CAPACITOR SUBCOMMITTEE

F. V. Smith, *Chairman;* Sargent and Lundy, 140 South Dearborn Street, Chicago 3, Ill.
Glen Appleman Allentown, Pa.
C. E. Baugh San Francisco, Calif.
P. L. Bellaschi Portland, Oreg.
H. V. Dryer So. Milwaukee, Wis.
K. B. Hapgood Chattanooga, Tenn.
E. R. Hendrickson Maywood, Ill.
R. E. Marbury East Pittsburgh, Pa.
D. B. Masters Jackson, Mich.
N. A. Miller Chicago, Ill.
R. B. Miller Davenport, Iowa
C. E. Parks Indianapolis, Ind.
Leon Podolsky North Adams, Mass.
F. F. Schaller, Jr. Boston, Mass.
M. E. Scoville Pittsfield, Mass.
E. C. Starr Corvallis, Oreg.

DISTRIBUTION SUBCOMMITTEE

T. J. Brosnan, *Chairman;* Niagara Mohawk Power Corporation, 300 Electric Building, Buffalo, N. Y.
C. E. Baugh San Francisco, Calif.
H. C. Bingham Cleveland, Ohio
D. K. Blake Schenectady, N. Y.
Bryce Brady Oklahoma City, Okla.
Harold Cole Detroit, Mich.
H. L. Davis Philadelphia, Pa.
E. R. Hendrickson Maywood, Ill.
J. B. Hodtum Pittsburgh, Pa.
E. K. Huntington Rochester, N. Y.
C. H. Kraft St. Louis, Mo.
J. E. O'Brien Washington, D. C.
E. W. Oesterreich Pittsburgh, Pa.
J. S. Parsons East Pittsburgh, Pa.
E. V. Sayles Jackson, Mich.

GENERAL SYSTEMS SUBCOMMITTEE

R. L. Witzke, *Chairman;* Industry Engineering Department, Westinghouse Electric Corporation, East Pittsburgh, Pa.
P. W. Blye New York, N. Y.
R. W. Caswell Chicago, Ill.
F. L. Code Toronto, Ontario, Canada
O. A. Demuth Portland, Oreg.
R. G. Hooke Newark, N. J.
E. K. Huntington Rochester, N. Y.
I. B. Johnson Schenectady, N. Y.
A. A. Kroneberg Los Angeles, Calif.
L. B. LeVesconte Chicago, Ill.
L. M. Robertson Denver, Colo.

LIGHTNING AND INSULATOR SUBCOMMITTEE

J. T. Lusignan, *Chairman;* Ohio Brass Company, Engineering Department, Mansfield, Ohio
L. V. Bewley Bethlehem, Pa.
H. N. Ekvall Philadelphia, Pa.
H. A. Frey Baltimore, Md.
I. W. Gross New York, N. Y.
J. H. Hagenguth Pittsfield, Mass.
K. J. Harder East Pittsburgh, Pa.
W. W. Lewis Schenectady, N. Y.
H. L. Rorden Portland, Oreg.
S. K. Waldorf Baltimore, Md.
E. R. Whitehead Chicago, Ill.

TOWERS, POLES, AND CONDUCTORS SUBCOMMITTEE

A. E. Davison, *Chairman;* Hydro-Electric Power Commission of Ontario, 620 University Ave., Toronto, Ontario, Canada
N. K. Barr Newark, Ohio
A. E. Beattie Beaumont, Texas
H. W. Bakeborn Newark, Ohio
A. A. Booker Boston, Mass.
P. J. Croft Toronto, Ontario, Canada
A. L. Duna Worcester, Mass.
K. E. Hapgood Chattanooga, Tenn.
E. L. Kanouse Los Angeles, Calif.
W. H. Knutz Hammond, Ind.
J. E. O'Brien Washington, D. C.
A. A. Osipovich Portland, Oreg.
F. W. Packer Allentown, Pa.
T. F. Peterson Cleveland, Ohio
J. A. Rawls Richmond, Va.
L. M. Robertson Denver, Colo.
A. S. Runciman Montreal, Quebec, Canada
A. N. Shealy Baltimore, Md.
E. J. Staubitz Pittsburgh, Pa.
Joel Tompkins Massena, N. Y.
F. Von Voigtlander Jackson, Mich.
R. G. Yerke Seward, Neb.

Science and Electronics Division

Basic Sciences

APPLIED MATHEMATICS SUBCOMMITTEE

M. G. Malti, *Chairman;* School of Electrical Engineering, Cornell University, Ithaca, N. Y.

Mathematicians

Garrett Birkhoff Cambridge, Mass.
D. G. Bourgin Urbana, Ill.
R. J. Duffin Pittsburgh, Pa.
A. E. Hines Pittsburgh, Pa.
Mark Kac Ithaca, N. Y.
John Von Neumann Princeton, N. J.
Harry Pollard Ithaca, N. Y.
J. J. Stoker New York, N. Y.
J. W. Tukey Princeton, N. J.
D. V. Widder Cambridge, Mass.
Norbert Wiener Cambridge, Mass.
Max Woodbury Princeton, N. J.

Electrical Engineers

P. L. Alger Schenectady, N. Y.
Murray Gardner Cambridge, Mass.
H. B. Hansteen New York, N. Y.
E. W. Kimbark Evanston, Ill.
Louis Pipes Los Angeles, Calif.
Joseph Slepian East Pittsburgh, Pa.
J. J. Smith Schenectady, N. Y.
Harry Sohon Philadelphia, Pa.

ELECTRIC CIRCUIT THEORY SUBCOMMITTEE

H. J. Carlin, *Chairman;* Microwave Research Institute, Polytechnic Institute of Brooklyn, Brooklyn, N. Y.
J. G. Brainerd Philadelphia, Pa.
R. L. Dietzold Murray Hill, N. J.
M. J. Di Toro Nutley, N. J.
A. B. Giordano Brooklyn, N. Y.
E. A. Guillemin Cambridge, Mass.
T. J. Higgins Madison, Wis.
F. F. Ordung New Haven, Conn.
W. O. Osbon East Pittsburgh, Pa.
M. B. Reed Urbana, Ill.
H. I. Tarpley State College, Pa.
Ernst Weber Brooklyn, N. Y.

ELECTRICAL PROPERTIES OF GASES SUBCOMMITTEE

T. B. Jones, *Chairman;* School of Electrical Engineering, Johns Hopkins University, Baltimore 18, Md.
J. D. Cobine Schenectady, N. Y.
L. H. Fisher New York, N. Y.
L. H. Germer Murray Hill, N. J.
Joseph Slepian East Pittsburgh, Pa.

ELECTRICAL PROPERTIES OF SOLIDS AND LIQUIDS SUBCOMMITTEE

C. Bradner Brown, *Chairman;* Naval Gun Factory, United States Naval Ordnance Laboratory, White Oak, Md.
J. A. Becker Murray Hill, N. J.
F. M. Clark Schenectady, N. Y.
W. C. Dunlap Schenectady, N. Y.
R. W. Engstrom Lancaster, Pa.
K. Lark-Horovitz Lafayette, Ind.
P. H. Miller, Jr. Philadelphia, Pa.
Fred Seitz Pittsburgh, Pa.
Lloyd Smith Ithaca, N. Y.
A. von Hippel Cambridge, Mass.
D. E. Wooldridge Culver City, Calif.

ENERGY SOURCES SUBCOMMITTEE

L. W. Matsch, *Chairman;* Illinois Institute of Technology, Department of Electrical Engineering, Chicago 16, Ill.
W. C. Brown Point Mugu, Calif.
M. A. Garstens Washington, D. C.
W. A. Lewis, Jr. Chicago, Ill.
Walther Richter Milwaukee, Wis.
J. J. Smith Schenectady, N. Y.
B. R. Teare Pittsburgh, Pa.
J. D. Tebo New York, N. Y.
Milton Tenzer Bradley Beach, N. J.

MAGNETICS SUBCOMMITTEE

R. M. Bozorth, *Chairman;* Bell Telephone Laboratories, Inc., Murray Hill, N. J.
R. A. Chegwidden, *Secretary* Murray Hill, N. J.
F. G. Brockman Irvington-on-Hudson, N. Y.
G. H. Cole Middletown, Ohio
E. A. Gaugler Silver Spring, Md.
J. E. Goldman Pittsburgh, Pa.
W. Morrill Pittsfield Pa.
W. E. Ruder Schenectady, N. Y.
C. W. Stoker Pittsburgh, Pa.

Computing Devices

ANALOG COMPUTERS SUBCOMMITTEE

E. L. Harder, *Chairman;* Industry Engineering Department 11-L, Westinghouse Electric Corporation, East Pittsburgh, Pa.
J. F. Calvert Evanston, Ill.
A. C. Hall Cambridge, Mass.
G. D. McCann Pasadena, Calif.
V. Paschkis New York, N. Y.
F. S. Rothe Schenectady, N. Y.
H. G. Tremblay Johnsville, Pa.

DIGITAL COMPUTERS SUBCOMMITTEE

S. N. Alexander, *Chairman;* National Bureau of Standards, Electronic Computers Section, Washington 25, D. C.
H. P. Kuehni Schenectady, N. Y.
J. W. Mauchly Philadelphia, Pa.
G. D. McCann Pasadena, Calif.
J. C. McPherson New York, N. Y.
P. L. Morton Berkeley, Calif.
R. L. Snyder Aberdeen Proving Ground, Md.

COMPUTER BIBLIOGRAPHY SUBCOMMITTEE

W. H. MacWilliams, Jr., *Chairman;* Bell Telephone Laboratories, Inc., Whippany, N. J.

Electronic Power Converters

ADMINISTRATIVE SUBCOMMITTEE

Main Committee Officers:
C. C. Herskind, *Chairman;* General Electric Company, Power Electronics Division, Schenectady 5, N. Y.

W. N. Farquhar, *Vice-Chairman* Pittsburgh, Pa.
C. R. Marcum, *Secretary* East Pittsburgh, Pa.
Harold Winograd, *Preceding Chairman* Milwaukee, Wis.

Subcommittee Chairmen:
I. K. Dortort Philadelphia, Pa.
R. A. Nelson Pittsfield, Mass.
Waldo Porter Vancouver, Wash.
August Schmidt, Jr. Schenectady, N. Y.
J. C. Walter Camden, N. J.

ELECTRONIC CONVERTER APPLICATION SUBCOMMITTEE

W. N. Farquhar, *Chairman;* Aluminum Company of America, 801 Gulf Building, Pittsburgh 19, Pa.
C. E. Buterbaugh
E. H. Cox, Jr. Baton Rouge, La.
F. W. Cramer Pittsburgh, Pa.
J. R. Donnelly Philadelphia, Pa.
N. W. Geist
W. E. Gutzwiller Milwaukee, Wis.
R. N. Hunter New York, N. Y.
Armin Leuthold Mt. Royal, Quebec, Canada
W. E. Bloecker New York, N. Y.
W. J. L. Rupprecht Midland, Mich.
S. L. Smith Philadelphia, Pa.
O. J. Swanson Gary, W. Va.
J. T. Thwaites Hamilton, Ontario, Canada
J. W. Ward Sylacauga, Ala.

ELECTRONIC CONVERTER CIRCUITS SUBCOMMITTEE

I. K. Dortort, *Chairman;* ITE Circuit Breaker Company, 19th & Hamilton Streets, Philadelphia 30, Pa.
W. F. Bonner Clifton, N. J.
J. L. Boyer East Pittsburgh, Pa.
G. N. Hughes Alcoa, Tenn.
Otto Jensen Philadelphia, Pa.
G. F. Jones East Pittsburgh, Pa.
W. E. Bloecker New York, N. Y.
A. H. Mittag Schenectady, N. Y.
R. A. Nelson Pittsfield, Mass.
M. E. Reagan East Pittsburgh, Pa.
August Schmidt, Jr. Schenectady, N. Y.
C. H. Willis Princeton, N. J.

Working Group:
Mechanical Rectifiers
Otto Jensen, *Chairman;* ITE Circuit Breaker Company, 19th & Hamilton Streets, Philadelphia 30, Pa.
I. K. Dortort Philadelphia, Pa.
D. H. Smith New York, N. Y.

PAPERS AND SPEAKERS SUBCOMMITTEE

August Schmidt, Jr., *Chairman;* General Electric Company, 1 River Road, Schenectady 5, N. Y.
J. B. Rice West Allis, Wis.
J. T. Thwaites Hamilton, Ontario, Canada
H. E. Zuvers Schenectady, N. Y.

RECTIFIER TRANSFORMERS SUBCOMMITTEE

R. A. Nelson, *Chairman;* General Electric Company, 100 Woodlawn Avenue, Pittsfield, Mass.
F. D. Kaiser Sharon, Pa.
A. J. Maslin Sharon, Pa.
W. C. Sealey Milwaukee, Wis.

RECTIFYING DEVICES SUBCOMMITTEE

Harold Winograd, *Chairman;* Allis-Chalmers Manufacturing Company, Electrical Department, Milwaukee 1, Wis.
D. V. Edwards Newark, N. J.
D. E. Marshall Bloomfield, N. J.
August Schmidt, Jr. Schenectady, N. Y.
H. C. Steiner Schenectady, N. Y.

WEST COAST SUBCOMMITTEE

Waldo Porter, *Chairman;* Aluminum Company of America, P. O. Box 120, Vancouver, Wash.
W. M. Allen Portland, Oreg.
E. D. Barens Los Angeles, Calif.
E. S. Benson San Francisco, Calif.
H. L. Burris Pittsburg, Calif.
R. J. Corfield Garfield, Utah
J. H. Cox Sunnyvale, Calif.
R. H. Denyer Portland, Oreg.
A. G. Dickinson Trail, British Columbia, Canada
E. F. Donatic Ontario, Calif.
Alex. Dovjikov Portland, Oreg.
R. H. Duguid Los Angeles, Calif.
S. R. Durand Milwaukee, Wis.
L. E. Dye Los Angeles, Calif.
T. F. Hadwin Vancouver, British Columbia, Canada
D. R. Hoopes Salt Lake City, Utah
J. V. Kresser San Francisco, Calif.
C. A. Langloid Portland, Oreg.
H. F. Lickey Pullman, Wash.
M. McCoy Portland, Oreg.
A. L. Munn San Leandro, Calif.
S. J. Pope Spokane, Wash.
H. H. Skilling Stanford, Calif.
E. C. Starr Corvallis, Oreg.
H. V. Strandberg Seattle, Wash.
J. R. Tenney Geneva, Utah

HOT-CATHODE POWER CONVERTER SUBCOMMITTEE

J. C. Walter, *Chairman;* Radio Corporation of America, Camden, N. J.
R. W. Barker Pittsfield, Mass.
W. H. Bixby Detroit, Mich.
H. R. Butler Newark, N. J.
F. W. Cramer Pittsburgh, Pa.
D. V. Edwards Newark, N. J.
C. E. Hamann Lynn, Mass.
J. F. Harris Newark, N. J.
E. W. Hutton Schenectady, N. Y.
W. E. Large East Pittsburgh, Pa.
F. G. Logan St. Louis, Mo.
E. J. Rathsack Milwaukee, Wis.
F. M. Rives Schenectady, N. Y.
W. C. Rudd Larchmont, N. Y.
J. W. Sanborn Camden, N. J.
D. H. Smith Schenectady, N. Y.
H. C. Steiner Schenectady, N. Y.
H. L. Thorson Schenectady, N. Y.
D. E. Trucksess New York, N. Y.

Electronics

ELECTRON TUBES SUBCOMMITTEE

H. C. Steiner, *Chairman;* Electronics Department, I. & T. Tube Division, General Electric Company, Schenectady 5, N. Y.
A. Y. Bentley Passaic, N. J.
W. R. Clark Philadelphia, Pa.
F. W. Cramer Pittsburgh, Pa.
D. V. Edwards Newark, N. J.
A. V. Glover Lancaster, Pa.
R. E. Graham Kew Gardens, N. Y.
William Happe, Jr. Clifton, N. J.
L. B. Headrick Lancaster, Pa.
Scott Helt Passaic, N. J.
J. H. Hutchings Geneva, Ill.
K. S. Koon Endicott, N. Y.
O. W. Livingston Schenectady, N. Y.
C. R. Marcum East Pittsburgh, Pa.
D. E. Marshall Bloomfield, N. J.
August Schmidt, Jr. Schenectady, N. Y.
Thomas Spooner East Pittsburgh, Pa.
J. T. Thwaites Hamilton, Ontario, Canada
Simeon Weston Brooklyn, N. Y.
W. C. White Schenectady, N. Y.
C. H. Willis Princeton, N. J.
Harold Winograd Milwaukee, Wis.

X-RAY TUBES, APPARATUS AND APPLICATIONS SUBCOMMITTEE

Scott W. Smith, *Chairman;* X-Ray Section, National Bureau of Standards, Washington 25, D. C.
Z. J. Atlee Chicago, Ill.
Arthur Klinckermann Chicago, Ill.
Joseph Lempert Bloomfield, N. J.
G. E. Maxim Cleveland, Ohio
T. H. Rogers Springdale, Conn.
David Susin Covington, Ky.
Robert F. Wilson Milwaukee, Wis.

ELECTROSTATIC PROCESSES SUBCOMMITTEE

G. W. Hewitt, *Chairman;* Research Laboratories, Westinghouse Electric Corporation, East Pittsburgh, Pa.
J. O. Amtus Troy, N. Y.
J. E. Coolidge, Jr. State College, Pa.
E. P. Miller Indianapolis, Ind.
H. V. Nelson Schenectady, N. Y.
S. R. Orens, Jr. Greenwich, Conn.
G. W. Penney Pittsburgh, Pa.
E. R. Thomas New York, N. Y.
J. B. Thomas Fort Worth, Texas
H. J. White Bound Brook, N. J.

HIGH FREQUENCY CONDUCTORS, CABLES, AND CONNECTORS SUBCOMMITTEE

G. J. Crowdes, *Chairman;* Simplex Wire and Cable Company, 79 Sidney Street, Cambridge 39, Mass.
W. R. Dohan Camden, N. J.
E. W. Greenfield Hastings-on-Hudson, N. Y.
J. D. Heibel Erie, Pa.
B. A. Jackson New York, N. Y.
W. J. King Murray Hill, N. J.
H. B. Slade Passaic, N. J.
W. R. Thurston Cambridge, Mass.

LIAISON WITH NUCLEONICS SUBCOMMITTEE

G. A. Morton, *Chairman;* R. C. A. Laboratories, Princeton, N. J.

ELECTRONIC AIDS TO NAVIGATION SUBCOMMITTEE

H. R. Mimno, *Chairman,* Cruft Laboratory, Harvard University, Cambridge 38, Mass.

ELECTRONIC AIDS TO GEOPHYSICS SUBCOMMITTEE

L. G. Cowles, *Chairman;* The Superior Oil Company, Houston, Texas

INFRARED APPLICATIONS SUBCOMMITTEE

A. H. Canada, *Chairman;* General Engineering and Consulting Laboratory, General Electric Company, Schenectady 5, N. Y.
A. R. Dennett Newport, R. I.
William A. Dynes Dayton, Ohio
W. G. Fastie Philadelphia, Pa.
B. J. Goldfarb Dayton, Ohio
E. D. Wilson East Pittsburgh, Pa.
C. S. Woodside Washington, D. C.

ELECTRONIC METHODS IN FOOD AND BIOLOGICAL PROCESSING SUBCOMMITTEE

T. H. Morris, *Chairman;* Department of Electrical Engineering, Stanford Research Institute, Stanford, Calif.

MAGNETIC AMPLIFIERS SUBCOMMITTEE

E. L. Harder, *Chairman;* Westinghouse Electric Corporation, East Pittsburgh, Pa.
E. V. Weir, *Secretary* Silver Spring, Md.
A. O. Black Butler, Pa.
L. W. Buechler St. Louis, Mo.
W. J. Dornhoefer St. Louis, Mo.
L. A. Finzi Pittsburgh, Pa.
A. S. Fitzgerald San Francisco, Calif.
W. A. Geyger Silver Spring, Md.
A. B. Haines Murray Hill, N. J.
J. E. Hart Washington, D. C.
A. D. Hitt, Jr. Washington, D. C.
W. C. Johnson Princeton, N. J.
R. E. Morgan Schenectady, N. Y.
H. B. Rex Washington, D. C.
P. L. Schmidt East Pittsburgh, Pa.
R. W. Wolke Schenectady, N. Y.
D. W. VerPlanck Pittsburgh, Pa.

Working Groups:

(1) Definitions
W. J. Dornhoefer, *Sponsor* St. Louis, Mo.
E. L. Harder East Pittsburgh, Pa.
L. A. Finzi Pittsburgh, Pa.
A. B. Haines Murray Hill, N. J.
E. B. McDowell Schenectady, N. Y.
E. V. Weir Silver Spring, Md.

(2) Speed of Response, Figure of Merit
L. A. Finzi, *Sponsor* Pittsburgh, Pa.
E. L. Harder East Pittsburgh, Pa.
W. J. Dornhoefer St. Louis, Mo.
W. C. Johnson Princeton, N. J.
R. E. Morgan Schenectady, N. Y.
H. B. Rex Washington, D. C.
D. W. VerPlanck Pittsburgh, Pa.
E. V. Weir Silver Spring, Md.

(3) Ratings
R. W. Wolke, *Sponsor* Schenectady, N. Y.
W. J. Dornhoefer St. Louis, Mo.
L. A. Finzi Pittsburgh, Pa.
E. L. Harder East Pittsburgh, Pa.
J. E. Hart Washington, D. C.
R. E. Morgan Schenectady, N. Y.

ELECTRONIC APPLICATIONS OF SEMICONDUCTOR DEVICES SUBCOMMITTEE

C. Bradner Brown, *Chairman;* Naval Ordnance Laboratory, White Oak, Md.
Harold Goldberg Washington, D. C.
J. R. Hyneman New York, N. Y.
G. D. O'Neill Kew Gardens, N. Y.

LIAISON WITH ELECTRONIC HEATING SUBCOMMITTEE

T. P. Kinn, *Chairman;* Electronics and X-Ray Division, Westinghouse Electric Corporation, 2519 Wilkens Avenue, Baltimore 3, Md.
R. M. Baker Baltimore, Md.
W. C. Rudd Larchmont, N. Y.

ELECTRONIC SYSTEMS ENGINEERING SUBCOMMITTEE

H. L. Flowers, *Chairman;* Aerophysics Department, Goodyear Aircraft Corporation, Akron 15, Ohio
(Personnel to be selected)

ELECTRONIC STANDARDS AND DEFINITIONS SUBCOMMITTEE

(Personnel to be selected)

LIAISON WITH IRE SUBCOMMITTEE

R. S. Burnap, *Chairman;* Radio Corporation of America, R. C. A. Victor Division, Harrison, N. J.

LIAISON WITH JETEC SUBCOMMITTEE

(Personnel to be selected)

EDUCATION IN ELECTRONICS SUBCOMMITTEE

J. D. Ryder, *Chairman;* University of Illinois, Urbana, Ill.
E. M. Boone Columbus, Ohio
M. A. Honnell Atlanta, Ga
R. K. Northrop Ithaca, N. Y.
A. J. Quigley Notre Dame, Ind
J. T. Thwaites Hamilton, Ont., Canada
D. G. Wilson Lawrence, Kansas

PAPERS REVIEW SUBCOMMITTEE

W. C. White, *Chairman;* General Electric Research Laboratory, The Knolls, Schenectady, N. Y.
G. M. K. Baker Princeton, N. J.
W. R. Clark Philadelphia, Pa.
H. F. Dart Bloomfield, N. J.
Rudolf Feldt Clifton, N. J.
R. E. Graham Kew Gardens, N. Y.
S. B. Ingram New York, N. Y.
L. A. Kilgore East Pittsburgh, Pa.
H. L. Palmer Schenectady, N. Y.
H. C. Steiner Schenectady, N. Y.
Dayton Ulrey Lancaster, Pa.
Harold Winograd Milwaukee, Wis.

Instruments and Measurements

ORGANIZATION SUBCOMMITTEE

T. S. Gray, *Chairman;* Massachusetts Institute of Technology, Cambridge 39, Mass.
C. F. Savage, *Secretary* Lynn, Mass.
E. I. Green Murray Hill, N. J.
H. C. Koenig New York, N. Y.
G. Reid, Jr. Washington, D. C.

DEFINITIONS SUBCOMMITTEE

C. L. Dawes, *Chairman;* Harvard University, Cambridge 39, Mass.
J. E. Clem Schenectady, N. Y.
A. B. Craig Boston, Mass.
H. C. Dickinson Lynn, Mass.
W. N. Goodwin, Jr. Newark, N. J.
Everett S. Lee Schenectady, N. Y.
R. E. Lenehan Newark, N. J.
F. B. Silsbee Washington, D. C.

ELECTRICAL TESTS ON DIELECTRICS IN THE FIELD SUBCOMMITTEE

F. C. Doble, *Chairman;* Doble Engineering Company, Box 544, Belmont 78, Mass.
W. G. Amey Philadelphia, Pa.
D. L. Brown Portland, Oreg.
A. L. Brownlee Chicago, Ill.
R. B. Curdts Philadelphia, Pa.
C. L. Dawes Cambridge, Mass.
W. F. Dunkle Hazleton, Pa.
I. G. Easton Cambridge, Mass.
W. N. Eddy Cambridge, Mass.
J. G. Ford Sharon, Pa.
I. W. Gross New York, N. Y.

Everett S. Lee Schenectady, N. Y.
W. N. Lindblad Emeryville, Calif.
G. M. L. Sommerman Evanston, Ill.
R. R. Thomas New York, N. Y.
L. Wetherill Pittsfield, Mass.

HIGH-FREQUENCY MEASUREMENTS SUBCOMMITTEE

Harold Lyons, *Chairman;* National Bureau of Standards, Microwave Measurement Laboratory, Washington, D. C.
S. L. Bailey Washington, D. C.
E. P. Felch, Jr. Murray Hill, N. J.
F. Hamburger, Jr. Baltimore, Md.
H. R. Meahl Schenectady, N. Y.
H. A. Wheeler Great Neck, N. Y.
A. J. Wing, Jr. Evanston, Ill.

INDUSTRIAL SPECTROSCOPY SUBCOMMITTEE

J. H. Enns, *Chairman;* Randall Laboratory, University of Michigan, Ann Arbor, Michigan
H. M. Bedell Cleveland, Ohio
G. D. Butler New York, N. Y.
D. K. Coles East Pittsburgh, Pa.
C. H. Corliss Washington, D. C.
H. M. Crosswhite Baltimore, Md.
W. G. Fastie Philadelphia, Pa.
W. D. Hershberger Berkeley, Calif.
E. K. Jaycox Murray Hill, N. J.
L. W. McNair Wood River, Ill.
John Sterner Cambridge, Mass.
J. Sherman Philadelphia, Pa.
Van Zandt Williams Glenbrook, Conn.

MARKING OF VARMETERS AND RELATED INSTRUMENTS SUBCOMMITTEE

A. B. Craig, *Chairman;* Boston Edison Company, 39 Boylston Street, Boston 12, Mass.
A. L. Brownlee Chicago, Ill.
A. L. Carvill Lynn, Mass
W. G. Knickerbocker Detroit, Mich.
A. E. Knowlton New York, N. Y.
F. A. Redding Los Angeles, Calif.
F. B. Silsbee Washington, D. C.
H. B. Smith Buffalo, N. Y.

MASTER TEST CODE FOR POWER MEASUREMENTS SUBCOMMITTEE

C. J. Zeller, *Chairman;* Consolidated Edison Company of New York, Inc., 708—1st Avenue, New York 17, N. Y.
W. G. Knickerbocker Detroit, Mich.
H. C. Koenig New York, N. Y.
B. E. Lenehan Newark, N. J.
L. W. Matsch Chicago, Ill.
J. H. Miller Newark, N. J.
C. F. Savage, Jr. West Lynn, Mass.
Harry Sohon Philadelphia, Pa.
L. N. Stone Corvallis, Oreg.

MASTER TEST CODE FOR TEMPERATURE MEASUREMENTS SUBCOMMITTEE

L. A. Burckmyer, Jr., *Chairman;* Cornell University, Ithaca, New York
P. A. Borden Waterbury, Conn.
E. D. Doyle Philadelphia, Pa.
J. L. Fuller Cleveland, Ohio
W. R. Hough Cleveland, Ohio
A. K. Joecks New York, N. Y.
S. S. Stack Schenectady, N. Y.

REVISION OF STANDARD NUMBER 4 (MEASUREMENT OF TEST VOLTAGE IN DIELECTRIC TESTS) SUBCOMMITTEE

J. T. Lusignan, Jr., *Chairman;* Engineering Department, Ohio Brass Company, Mansfield, Ohio
P. L. Bellaschi Portland, Oreg.
A. L. Brownlee Chicago, Ill.
J. S. Carroll Stanford University, Calif.
J. J. Clark East Pittsburgh, Pa.
E. W. Davis Cambridge, Mass.
C. M. Foust Schenectady, N. Y.
H. A. Frey Baltimore, Md.
I. W. Gross New York, N. Y.
J. H. Hagenguth Pittsfield, Mass.
W. B. Kouwenhoven Baltimore, Md.
R. L. Lapp LeRoy, N. Y.
W. W. Lewis Schenectady, N. Y.
M. Newman Minneapolis, Minn.
J. H. Park Washington, D. C.
W. C. Sealey Milwaukee, Wis.
W. T. Smith Arlington, Va.
R. W. Sorensen Pasadena, Calif.
W. L. Teague Sharon, Pa.
S. W. Zimmerman Ithaca, N. Y.

WATT-HOUR METERS SUBCOMMITTEE

C. F. Savage, Jr., *Chairman;* General Electric Company, 40 Federal Street, West Lynn, Mass.
H. A. Brown Rochester, N. Y.
G. N. Burkhart, Jr. Lafayette, Ind.
D. T. Canfield Lafayette, Ind.
A. B. Craig Boston, Mass.
F. C. Holtz Springfield, Ill.
W. G. Knickerbocker Detroit, Mich.
H. C. Koenig New York, N. Y.
B. E. Lenehan Newark, N. J.
W. N. Lindblad Emeryville, Calif.
F. H. Rogers Baltimore, Md.
K. M. Stevens Alhambra, Calif.
M. B. Stout Ann Arbor, Mich.
J. M. Vanderleck Toronto, Ontario, Canada

CO-OPERATION WITH INSTRUMENT SOCIETY OF AMERICA SUBCOMMITTEE

A. J. Hornfeck, *Chairman;* Bailey Meter Company, 1050 Ivanhoe Road, Cleveland 10, Ohio
J. J. Bowen Buffalo, N. Y.
C. J. Brumbaugh Hamburg, N. Y.
F. C. Rushing Buffalo, N. Y.

Metallic Rectifiers

TECHNICAL INFORMATION SUBCOMMITTEE

C. E. Hamann, *Chairman;* Rectifier Division, General Electric Company, 930 Western Avenue, Lynn 3, Mass.
M. E. Gamble Indianapolis, Ind.
L. K. Hedding Pittsburgh, Pa.
J. L. Wagner Endicott, N. Y.

MINIATURE RECTIFIERS SUBCOMMITTEE

P. G. Cobb, *Chairman;* Weston Electrical Instrument Corporation, 614 Frelinghuysen Avenue, Newark 5, N. J.

DEFINITIONS SUBCOMMITTEE

D. E. Truckess, *Chairman;* Bell Telephone Laboratories, Inc., 463 West Street, New York 14, N. Y.
W. F. Bonner Clifton, N. J.
C. W. Hansell Rocky Point, L. I., N. Y.

BIBLIOGRAPHY SUBCOMMITTEE

E. A. Harty, *Chairman;* Rectifier Engineering Division, General Electric Company, River Works, West Lynn 3, Mass.

TEST CODE SUBCOMMITTEE

W. F. Bonner, *Chairman;* Selenium-Intelin Division, Federal Telephone and Radio Corporation, 100 Kingsland Avenue, Clifton, N. J.
J. T. Cataldo Fort Monmouth, N. J.
K. S. Geiges New York, N. Y.

PATENTS SUBCOMMITTEE

Glen Ramsey, *Chairman;* Fansteel Metallurgical Corporation, Rectifier Division, North Chicago, Ill.

PAPERS AND MEETINGS SUBCOMMITTEE

L. W. Burton, *Chairman;* General Electric Company, River Works, 920 Western Avenue, Lynn, Mass.
E. A. Groeteke St. Louis, Mo.
Glen Ramsey North Chicago, Ill.

Nucleonics

ISOTOPIC TRACERS SUBCOMMITTEE

R. E. Watson, *Chairman;* Research Department, Leeds and Northrup Company, 4901 Stenton Avenue, Philadelphia 44, Pa.
(Personnel to be selected)

NUCLEAR THEORY SUBCOMMITTEE

P. N. Ross, *Chairman;* Atomic Power Division, Westinghouse Electric Corporation, Bettis Field, P. O. Box 1468, Pittsburgh 30, Pa.

NUCLEAR MACHINES SUBCOMMITTEE

J. G. Hutton, *Chairman;* General Engineering and Consulting Laboratory, General Electric Company, Schenectady 5, N. Y.
(Personnel to be selected)

Therapeutics

No subcommittees

Joint Subcommittees

JOINT SUBCOMMITTEE ON APPLICATIONS OF PROBABILITY METHODS TO POWER-SYSTEM PROBLEMS (JOINT WITH POWER GENERATION AND SYSTEM ENGINEERING COMMITTEES)

G. Calabrese, *Chairman;* Electrical Engineering Department, New York University, University Heights, New York 53, N. Y.
W. R. Blakely Toronto, Ontario, Canada
V. M. Cook New York, N. Y.
Howard Duryea Birmingham, Ala.
R. G. Hooke Newark, N. J.
H. A. Lott Los Angeles, Calif.
F. J. Leerburger New York, N. Y.
W. J. Lyman Pittsburgh, Pa.
Bela Mohr Oklahoma City, Okla.
H. W. Phillips Philadelphia, Pa.
H. B. Smith Buffalo, N. Y.
V. A. Thiemann New York, N. Y.
C. W. Watchorn Baltimore, Md.

JOINT SUBCOMMITTEE ON ELECTRICAL AIDS TO MEDICINE (JOINT WITH ELECTRONICS, INSTRUMENTS AND MEASUREMENTS, AND THERAPEUTICS COMMITTEES)

Kendrick Hare, *Chairman;* Childrens' Hospital, 219 Bryant Street, Buffalo 9, N. Y.
G. W. Dunlap Schenectady, N. Y.
W. A. Geohegan New York, N. Y.
Harry Grundfest New York, N. Y.
J. P. Hervey Baltimore, Md.
R. S. Mackay Berkeley, Calif.
G. A. Morton Princeton, N. J.
J. G. Reid, Jr. Washington, D. C.
S. W. Smith Washington, D. C.
C. A. Tobias Berkeley, Calif.
S. R. Warren, Jr. Philadelphia, Pa.
A. M. Zarem Los Angeles, Calif.

JOINT SUBCOMMITTEE ON ELECTRONIC INSTRUMENTS (JOINT WITH ELECTRONICS AND INSTRUMENTS AND MEASUREMENTS COMMITTEES)

Rudolf Feldt, *Chairman;* Allen B. DuMont Laboratories, Inc., 1000 Main Avenue, Clifton, N. J.
W. H. Tidd, *Vice-Chairman* New York, N. Y.
P. K. McElroy, *Secretary* Cambridge, Mass.
M. J. Ackerman Camden, N. J.
G. E. Beggs Philadelphia, Pa.
Cledo Brunetti Stanford, Calif.
C. C. Chambers Philadelphia, Pa.
H. F. Dart Bloomfield, N. J.
G. W. Downs Pasadena, Calif.
G. V. Eltgroth Philadelphia, Pa.
E. R. Haberland Silver Spring, Md.
C. E. Hastings Hampton, Va.
C. M. Hathaway Denver, Colo.
D. M. Hill Boonton, N. J.
G. B. Hoadley Raleigh, N. C.
E. J. Isbister Great Neck, N. Y.
W. J. Jones Belmar, N. J.
N. W. Matthews Washington, D. C.
H. R. Meahl Schenectady, N. Y.
Edmund Osterland Boonton, N. J.
David Packard Palo Alto, Calif.
T. B. Perkins Harrison, N. J.
J. G. Reid, Jr. Washington, D. C.
E. R. Thomas New York, N. Y.
J. T. Thwaites Hamilton, Ontario, Canada
Howard Vollum Portland, Oreg.
A. H. Waynick State College, Pa.
W. P. Wills Philadelphia, Pa.

JOINT SUBCOMMITTEE ON NUCLEONIC INSTRUMENTS (JOINT WITH NUCLEONICS AND INSTRUMENTS AND MEASUREMENTS COMMITTEES)

G. A. Morton, *Chairman;* Radio Corporation of America, R.C.A. Laboratories Division, Princeton, N. J.
(Personnel to be selected)

JOINT SUBCOMMITTEE ON STANDARD FREQUENCY BANDS AND DESIGNATIONS

G. B. Ransom, *Chairman;* American Telephone and Telegraph Company, 32 Avenue of the Americas, New York 13, N. Y.
I. G. Easton Cambridge, Mass.
T. P. Kinn Baltimore, Md.
J. E. McCormack New York, N. Y.
F. B. Silsbee Washington, D. C.

JOINT SUBCOMMITTEE ON TELEMETERING (JOINT WITH INSTRUMENTS AND MEASUREMENTS AND SUBSTATIONS COMMITTEES)

W. J. Mayo-Wells, *Chairman;* Applied Physics Laboratory, The Johns Hopkins University, 8621 Georgia Avenue, Silver Spring 18, Md.
J. L. McKee, *Secretary* New York, N. Y.
J. L. Blackburn Newark, N. J.
P. A. Borden Waterbury, Conn.
M. A. Bostwick Portland, Oreg.
J. F. Brinster Princeton, N. J.
E. C. Brown Hartford, Conn.
W. A. Derr East Pittsburgh, Pa.
C. K. Duff Toronto, Ontario, Canada
A. J. Hornfeck Cleveland, Ohio
G. S. Lunge Schenectady, N. Y.
E. E. Lynch West Lynn, Mass.
W. E. Phillips Philadelphia, Pa.
Merle Robison Toledo, Ohio
G. M. Thynell Waterbury, Conn.
J. H. Vivian Los Angeles, Calif.
B. G. Walker Minneapolis, Minn.
C. E. Wiesgartner Cleveland, Ohio

Working Group on Telemetering Terms:
W. J. Mayo-Wells, *Chairman* Silver Spring, Md.
G. R. Anderson North Hollywood, Calif.
J. L. Blackburn Newark, N. J.
A. T. Gruer Albuquerque, N. M.
M. V. Kiebert Philadelphia, Pa.
R. L. Harding South Bend, Ind.
F. Lehan Pasadena, Calif.
E. E. Lynch West Lynn, Mass.
M. G. Pawley Washington, D. C.
J. M. Pearce Baltimore, Md.
W. E. Phillips Philadelphia, Pa.
G. M. Thynell Waterbury, Conn.
F. L. Verwiebe Silver Spring, Md.
G. F. G. Weedon Toronto, Ontario, Canada
W. A. Wildhack Washington, D. C.

JOINT SUBCOMMITTEE ON CARBON BRUSHES (JOINT AIEE TECHNICAL COMMITTEES ON AIR TRANSPORTATION AND ROTATING MACHINERY, AND IN CO-OPERATION WITH NEMA ON CODES)

T. M. Linville, *Chairman;* General Electric Company, 1 River Road, Schenectady 5, N. Y.
W. H. Austry St. Marys, Pa.
R. J. Biais New York, N. Y.
H. R. Brown Seattle, Wash.
W. E. Clancy St. Marys, Pa.
J. V. Dobson St. Marys, Pa.
H. M. Elsey East Pittsburgh, Pa.
D. E. Fritz Cleveland, Ohio
L. A. Heath Long Island City, N. Y.
B. C. Henry Ironton, Ohio
C. J. Herman Fort Wayne, Ind.
V. P. Hessler Urbana, Ill.
L. H. Hildebrandt Dayton, Ohio
H. T. Hulbert St. Marys, Pa.
R. E. Klokow Lima, Ohio
E. A. Lapham Long Island City, N. Y.
K. Lugosch Johnsville, Pa.
C. Lynn East Pittsburgh, Pa.
I. H. Manfredo Brooklyn, N. Y.
M. S. May St. Marys, Pa.
H. F. Mitchel Saginaw, Mich.
L. C. Novak West Lynn, Mass.
H. R. Partridge Boonton, N. J.
D. Ramadanoff Cleveland, Ohio
O. C. Rutledge Schenectady, N. Y.
S. D. Summers Washington, D. C.
F. R. Terrant Cleveland, Ohio
A. L. VanEmden Washington, D. C.
W. W. Walker Yonkers, N. Y.
